ABSTRACT

One-year measurements (October 2016–September 2017) of aerosol optical properties in the Athens urban environment were analyzed; for closure purposes, the results were supported by data of chemical composition of the non-refractory submicron aerosol fraction acquired with an Aerosol Chemical Speciation Monitor (ACSM). Both the spectral scattering (b_{sca}) and absorption (b_{abs}) coefficients exhibit a pronounced annual variability with higher values (63.6 Mm^{-1} at 550 nm and 41.0 Mm^{-1} at 520 nm, respectively) in winter, due to domestic heating releasing increased carbonaceous emissions and the shallow mixing layer trapping aerosols near the surface. Much lower values (33.5 Mm^{-1} and 22.9 Mm^{-1} for b_{sca} and b_{abs} , respectively) are found during summer, indicating rather aged aerosols from regional sources. The estimations of the dry spectral single scattering albedo (SSA), scattering (SAE) and absorption (AAE) Ångström exponents focus on the seasonality of the urban aerosols. The high SAE (~ 2.0) and low SSA (0.62 ± 0.11) values throughout the year indicate the dominance of fine-absorbing aerosols from fossil-fuel combustion, while the high AAE (~ 1.5) in winter suggests enhanced presence of biomass-burning aerosols. Pronounced morning and late evening/night peaks are found in both b_{sca} and b_{abs} during winter, coinciding with the morning traffic rush hour and increased residential wood burning in the evening, while in the other seasons, the diurnal patterns flatten out. The wind speed strongly affects the aerosol loading and properties in winter, since for winds below 3 m s^{-1} , a high increase in b_{sca} and b_{abs} is observed, consistent with low dilution processes and hazy/smoggy conditions. Our closure experiments indicate a good agreement ($R^2 = 0.91$, slope = 1.08) between the reconstructed and measured b_{sca} values and reveal that organic matter contributes about half of the sub-micron mass in winter, followed by sulfate ($\sim 40\%$) and nitrate (10%, only in winter) aerosols.

Keywords: Urban aerosols; Light scattering; Absorption; Chemical species; Wood burning; Athens.

INTRODUCTION

Atmospheric aerosols are one of the most important constituents in the earth-atmosphere system and climate (IPCC, 2013). Particulate matter ($\text{PM}_{2.5}$, PM_{10}), carbonaceous aerosols (Organic Matter (OM), Black Carbon (BC), Brown Carbon (BrC)) and gaseous air pollutants in urban environments contribute significantly to the light scattering and absorption processes, leading to large reduction in surface solar radiation, deterioration of visibility and air quality, and modification of the radiation and energy

balance with significant impacts on local and regional climate (Antón *et al.*, 2012; Bisht *et al.*, 2015; Valenzuela *et al.*, 2015; Zhang *et al.*, 2017). For assessing the climatic impact of aerosols, specific knowledge of the aerosol scattering (b_{sca}), absorption (b_{abs}) coefficients and single scattering albedo (SSA) is required (Moosmüller *et al.*, 2012; Dumka and Kaskaoutis, 2014). Aerosol studies over Greece mostly have focused on examining the columnar aerosol loading, physical-chemical and optical properties, types, source regions and climate implications (e.g., Gerasopoulos *et al.*, 2003, 2007, 2011; Papadimas *et al.*, 2012), while special attention has been given to Saharan dust storms (e.g., Gkikas *et al.*, 2013; Athanasopoulou *et al.*, 2016; Diapouli *et al.*, 2017a; Kosmopoulos *et al.*, 2017).

Apart from the decreasing trends in industrial and traffic emissions (NO_2 , SO_2) due to economic recession in Greece

E-mail address: nmihalo@noa.gr

(e.g., Vrekoussis *et al.*, 2013), the Athens Basin and other Greek cities experienced enhanced emissions of carbonaceous aerosols from bio-fuel and wood burning for residential heating during the last winter periods (Saffari *et al.*, 2013; Sarigiannis *et al.*, 2015; Gratsea *et al.*, 2017; Panopoulou *et al.*, 2017). In this line, synergy of ground-based measurements and modelling techniques has been utilized to study the carbonaceous-aerosol characteristics over Athens and to address their source apportionment and impact on regional air quality (e.g., Remoundaki *et al.*, 2013; Pateraki *et al.*, 2014; Saraga *et al.*, 2015; Triantafyllou *et al.*, 2016; Athanasopoulou *et al.*, 2017; Grivas *et al.*, 2018). Several studies have shown an increase in the carbonaceous-aerosol and PM concentrations during the recent years, especially during the winter periods (Paraskevopoulou *et al.*, 2014; Diapouli *et al.*, 2017b; Theodosi *et al.*, 2018), while recent BC source apportionment studies have shown that the wood burning emissions (BC_{wb}) contribute about 20–33% to the total BC mass in Athens Basin during wintertime (Diapouli *et al.*, 2017c; Fourtziou *et al.*, 2017; Kalogridis *et al.*, 2018). However, the near-surface aerosol optical and physical properties have not been evaluated so far, thus leaving a knowledge gap about their characteristics, seasonality and radiative impact. Few studies in the past examined the near-surface aerosol properties at the remote-coastal station of Finokalia, Crete (Sciare *et al.*, 2005; Vrekoussis *et al.*, 2005; Kalivitis *et al.*, 2011), while data from a suburban site (Democritos, Athens) has been involved in a European scale study (Pandolfi *et al.*, 2018), still not exploring the aerosol absorption characteristics or the SSA.

This study analyzes, for the first time, the annual characteristics of the near-surface extensive and intensive properties (i.e., b_{sca} , b_{abs} , SAE, AAE, SSA) of urban aerosols, obtained via systematic *in-situ* measurements in downtown Athens, aiming to examine the seasonality, the diurnal patterns, as well as to assess the influence of meteorology and emission sources, including residential wood burning, on aerosol loading and characteristics. Furthermore, it examines the role and contribution of major chemical species (organics, ammonium, sulfate, nitrate) on aerosol scattering.

STUDY LOCATION, MEASUREMENTS AND TECHNIQUES

Measuring Site

Measurements were conducted at the urban background station of the National Observatory of Athens (NOA; 37.97°N, 23.72°E, 105 m a.s.l.) at Thissio, a site that is considered as receptor of pollution plumes of different origins (Paraskevopoulou *et al.*, 2015; Theodosi *et al.*, 2018). This station is operated for measuring the background pollution levels in the Athens Basin and for assessing the sources of the transported aerosol plumes, since it is far from industries, main avenues and traffic zones (Gratsea *et al.*, 2017; Fourtziou *et al.*, 2017). More information about the morphology of the Athens Basin, the prevailing meteorological and dominant aerosol patterns can be found elsewhere (e.g., Kanakidou *et al.*, 2011; Theodosi *et al.*, 2011).

Instrumentation and Measurements

A three wavelength (450, 550, 700 nm) Integrating Nephelometer (model: TSI, 3563) was used for the measurement of the aerosol scattering coefficient (b_{sca} in Mm^{-1} ; between 7° and 170°) during the period October 2016–September 2017, averaged at 1-hour time intervals. As the grand majority (87%) of the Nephelometer measurements lies below 40% RH and 97% of the data lies below 50% RH, the derived aerosol properties that are analyzed in this study are regarded as corresponding to dry conditions. The Nephelometer was calibrated prior to the beginning of the measurements using CO₂ as the high span gas and air as the low span gas, with the calibration constant lying within ~2% and the overall uncertainty in the b_{sca} being ~7% (Heintzenberg *et al.*, 2006; Pandolfi *et al.*, 2018).

Continuous measurements of spectral aerosol absorption coefficient (b_{abs} in Mm^{-1}) were also carried out at NOA, Thissio, from October 2016 to September 2017, using a dual-spot seven-wavelength (370, 470, 520, 590, 660, 880 and 950 nm) Aethalometer (AE-33; Drinovec *et al.*, 2015). The AE-33 provides real-time measurements for the multiple scattering and loading effects using a dual-spot technology, where the incoming flow is split into two streams with unequal flows and passes through two spots on the same filter tape (Vaishya *et al.*, 2017; Kalogridis *et al.*, 2018). Therefore, AE-33 has the advantage of avoiding manual post-processing of the b_{abs} due to loading effect, while it uses an internal multiple-scattering correction of $C = 1.57$ (Drinovec *et al.*, 2015; Rajesh and Ramachandran, 2018). Some studies have shown that the $C = 1.57$ is small and results in overestimation of the b_{abs} (Collaud Coen *et al.*, 2010; Kumar *et al.*, 2018), while Rajesh and Ramachandran (2018) reported an overestimation of 28.5% in the b_{abs} from AE-33 against AE-31 in urban Ahmedabad, India. Although AE-33 initially measures the b_{abs} , the instrument output (BC in $\mu g m^{-3}$) is finally used for the estimation of the spectral b_{abs} via the mass absorption cross section (MAC) values (Backman *et al.*, 2017; Rajesh and Ramachandran, 2018):

$$b_{abs} = BC \times MAC \quad (1)$$

The MAC values for AE-33 at 370, 470, 880 and 950 nm were 18.47, 14.54, 7.77 and 7.16 $m^2 g^{-1}$, respectively, taken from the manufacturer. The overall uncertainty in the b_{abs} retrievals is in the range of 10–15% and seems to equally affect each wavelength, thus not altering the spectral dependence of the b_{abs} (Collaud Coen *et al.*, 2010; Sciare *et al.*, 2011).

Ancillary Measurements

On-Line Aerosol, Gaseous and Meteorological Measurements

Aerosol chemical composition analysis was performed using an Aerosol Chemical Speciation Monitor (ACSM; Ng *et al.*, 2011) that was collocated with the measurements of the aerosol optical properties. The ACSM measures the mass of particulate ammonium (NH_4^+), nitrate (NO_3^-), sulfate (SO_4^{2-}), chloride (Cl^-) and OM, providing near real-time chemical compositions at 30-min resolution. Details

about the ACSM measurements, time series and seasonal variability can be found elsewhere (Stavroulas *et al.*, 2018). The ACSM measurements were used for the reconstruction of the aerosol b_{sca} and to evaluate the contribution of each individual component on light scattering.

Complementary to the ACSM measurements, carbon monoxide (CO) and nitrogen monoxide (NO) were also monitored, at 1-min resolution, by a Horiba APMA-360 series automatic gas analyzer (scale: 0–10 ppmv, lower detectable limit: 0.2 ppmv, precision: ± 0.2 ppmv) and a Horiba APNA-360 series (chemiluminescence technique, scale: 0–1000 ppbv, lower detectable limit: 0.5 ppbv), respectively. PM_{10} concentrations were measured at 1-min resolution using a beta-attenuation monitor (Eberline, FH 62 I-R). Finally, meteorological data (ambient temperature, relative humidity, precipitation, wind speed (WS) and direction) at the sampling site were recorded by NOAA's automatic meteorological station (1-min resolution).

Off-Line Aerosol Measurements

$PM_{2.5}$ aerosol samples were collected using a Derenda particle sampler, with sampling time of 12 hours during the period November to February, and 24 hours during the remaining period (March to October). Samples were collected on 47-mm quartz filter samples (Tissuquartz, 2500QAT-UP, PALL). The $PM_{2.5}$ mass was determined by gravimetric analysis using an analytical microbalance with a precision of 1 μg ($\mu X-5$, Mettler-Toledo, Inc.). The filters were conditioned for 48 hours in controlled temperature ($20 \pm 3^\circ C$) and RH ($40 \pm 5\%$) conditions before pre- and post-weighing, according to the United States Environmental Protection Agency manual reference method: RFPS-1298-126 (Paraskevopoulou *et al.*, 2014).

Retrieved Parameters

The measured aerosol b_{sca} and b_{abs} are referred as “extensive properties” because they are linked to the number of aerosols in the atmosphere. These measurements were used to determine several other aerosol variables (known as “intensive properties”), such as the scattering Ångström exponent (SAE), absorption Ångström exponent (AAE) and SSA, which are related to size, shape, hygroscopic behavior, chemical composition and radiative impacts of aerosols rather than the aerosol loading (Dumka *et al.*, 2015). The SAE was calculated using the multi-wavelength Nephelometer b_{sca} measurements by applying the equation:

$$SAE = -\frac{\ln(b_{sca}(\lambda_1)/b_{sca}(\lambda_2))}{\ln(\lambda_1/\lambda_2)} \quad (2)$$

where λ_1 and λ_2 are the wavelengths corresponding to the pairs 450/550, 450/700 and 550/700 nm. SAE is an indicator of the dependence of scattering on particle size, with values higher than 1.5–2 implying scattering by submicron aerosols and values lower than 1 indicative of coarse particles (e.g., Valenzuela *et al.*, 2015).

Similarly, the AAE values were computed using the negative slope of a log-log plot of b_{abs} vs wavelength, as

$AAE = -d\ln(b_{abs}(\lambda))/d\ln(\lambda)$, in three wavelength bands, namely, 370–880 nm, 370–520 nm and 520–880 nm, in order to examine in higher detail the wavelength dependence of the absorption and the associated aerosol sources. Titos *et al.* (2017) also used the wavelength ranges 370–950 nm and 370–520 nm for the AAE estimates, since the $AAE_{370-520}$ is much more sensitive to changes in the spectral dependence of the b_{abs} at shorter wavelengths.

The spectral SSA was calculated as:

$$SSA = \frac{b_{sca}}{b_{sca} + b_{abs}} \quad (3)$$

at three wavelengths (450, 550 and 700 nm) coinciding with the Nephelometer b_{sca} values, by using concurrent measurements from the two instruments. The b_{abs} values at 450, 550 and 700 nm were estimated via the Ångström's formula using the neighboring b_{abs} values (i.e., 470, 520, 660 nm) and the AAE in the spectral band 370–880 nm. The SSA provides useful information about the relative contributions of scattering and absorption to total aerosol extinction, while it is also very important for aerosol radiative forcing and climate modelling studies (Hatzianastassiou *et al.*, 2004). Non-absorbing particles have SSA values close to 1, implying atmospheric cooling, while low SSA (< 0.6 – 0.7) refers to more absorbing aerosols, like BC, suggesting atmospheric warming (Bisht *et al.*, 2015; Tiwari *et al.*, 2016). The uncertainty in the computed SSA values, due to the combined effects of the measurement errors and uncertainties in the interpolation of the b_{abs} , ranges between 10% and 15%, with larger errors for low b_{sca} and b_{abs} values (Moorthy *et al.*, 2009). It should be noted that the derived aerosol properties (SAE, AAE, SSA) were calculated for the whole dataset of the hourly b_{sca} and b_{abs} values, since the latter are high enough (> 0.8 – $1.0 Mm^{-1}$) in order to provide estimations with limited uncertainties (Ealo *et al.*, 2018; Pandolfi *et al.*, 2018).

Chemical Reconstruction of Scattering

The reconstruction of the aerosol b_{sca} is performed via the formula proposed by Sciare *et al.* (2005), using the ACSM measurements on a daily basis:

$$b_{sca} = \alpha_{AS}[AS]f(RH) + \alpha_{POM}[POM] \quad (4)$$

where α_{AS} is the mass scattering efficiency (MSE) of ammonium sulfate (AS: $(NH_4)_2SO_4$) and $[AS]$ its mass concentration. $f(RH)$ is an empirical factor, i.e., the light-scattering enhancement factor that depends on RH, while α_{POM} and $[POM]$ are the MSE and mass concentration of particulate organic matter (POM), respectively. However, considering the presence of ammonium nitrate (AN: NH_4NO_3) during wintertime, the formula is adjusted as follows:

$$b_{sca} = \alpha_{AS}[AS]f(RH) + \alpha_{AN}[AN]f(RH) + \alpha_{POM}[POM] \quad (5)$$

where α_{AN} and $[AN]$ are the respective MSE and mass

concentration of ammonium nitrate. As the RH in the Nephelometer was kept below 40%, the measuring conditions are considered as dry and, therefore, $f(\text{RH}) = 1$ in Eqs. (4) and (5), indicating no light-scattering enhancement due to aerosol water uptake under humid conditions.

For the b_{sca} reconstruction, the values of $2.69 \text{ m}^2 \text{ g}^{-1}$ for the α_{AS} and $4.6 \text{ m}^2 \text{ g}^{-1}$ for the α_{POM} were used, as calculated from long-term measurements in Athens at 550 nm (August 2010–April 2013; Paraskevopoulou, 2014). These values are in accordance with MSE values of 2.66 and $4.19 \text{ m}^2 \text{ g}^{-1}$ for α_{AS} and α_{POM} , respectively, derived by Sciare *et al.* (2005) for the remote background site of Finokalia. The respective value for α_{AN} was taken as $2.7 \text{ m}^2 \text{ g}^{-1}$ from the reported global average. The MSE values for both AS and AN are in accordance with the average of $2.9 \pm 0.3 \text{ m}^2 \text{ g}^{-1}$ (range from 2.0 to $3.4 \text{ m}^2 \text{ g}^{-1}$) reported for α_{inorg} at 38 sites around the US (Malm and Hand, 2007). As MSE for POM might be site specific with respect to the sources and loadings, the current α_{POM} of $4.6 \text{ m}^2 \text{ g}^{-1}$ is in accordance with the

value of $3.81 \text{ m}^2 \text{ g}^{-1}$ derived by Malm and Hand (2007), based on prorating the AS mass scattering efficiency by the ratio of AS and POM densities. The α_{POM} in our case is also comparable to $4.5 \pm 0.73 \text{ m}^2 \text{ g}^{-1}$, reported by Cheng *et al.* (2015) for polluted environment in China, while an MSE value of $3.6 \text{ m}^2 \text{ g}^{-1}$ is reported by Ealo *et al.* (2018) for aged organics.

RESULTS AND DISCUSSIONS

Aerosol Scattering and Absorption Coefficients

This section analyzes the temporal variability of the aerosol b_{sca} and b_{abs} values as a function of their wavelength dependence, wind speed, boundary-layer dynamics and emission sources. The monthly variation of the spectral b_{sca} and b_{abs} in box-whisker charts is shown in Figs. 1(a) and 1(b), respectively. The average b_{sca} and b_{abs} values during the whole study period were $46.0 \pm 32.2 \text{ Mm}^{-1}$ and $28.4 \pm 36.3 \text{ Mm}^{-1}$, at the central wavelengths of 550 and 520 nm,

Fig. 1. Monthly values of the spectral (a) b_{sca} and (b) b_{abs} over Athens from October 2016 to September 2017. The box's upper and lower limits are the 75 and 25 percentiles, respectively, the black circle corresponds to the mean and the straight line denotes the median. The whiskers denote the 95 and 5 percentiles.

respectively (Table 1). In all months, the means are larger than the respective medians, indicating a tail towards large values of scattering and absorption (positive skewness), reflecting the episodic nature of high values, as also found at several European sites (Pandolfi *et al.*, 2018). The b_{sca} monthly means maximize in December and February (66.3 and 66.6 Mm^{-1} at 550 nm , respectively), while low plateau values are observed in the warm period (May–September, $30\text{--}35 \text{ Mm}^{-1}$ at 550 nm). In general, the monthly variation exhibits the same pattern regardless of the wavelength, but as the wavelength decreases the b_{sca} values and the corresponding ranges increase significantly due to higher sensitivity of scattering at shorter wavelengths (Fig. 1(a)). The larger range in the b_{sca} values from November to February indicates large variability in the local emission rates and in aerosol concentrations near the surface, while during spring and summer less variability exists, indicative of mostly regional-background conditions. A similar annual pattern is shown for the spectral b_{abs} that maximizes in December (mean of 47.8 Mm^{-1} at 520 nm) and presents lowest values in May (mean of 15.9 Mm^{-1} at 520 nm) (Fig. 1(b)). The remarkable monthly variability at 370 nm (means ranging from 24.2 Mm^{-1} to 97.8 Mm^{-1}) is highly weakened at 880 nm (means from 8.7 to 22.0 Mm^{-1}), indicative of large fraction and strong seasonality of the UV-absorbing aerosols. The large range in the winter months indicates local aerosol emissions from various sources with large fluctuation in the emission rates and/or influences from meteorology. Similar to our results, several urban and regional sites in Europe (Alsaadeh *et al.*, 2017) exhibited higher b_{sca} and b_{abs} values in winter compared to summer, due to lower dispersion, stagnant air masses and low-level temperature inversions (Putaud *et al.*, 2014; Pandolfi *et al.*, 2018).

The b_{sca} values at the urban/background site of Thissio are, in general, higher than most of those reported for 25 sites all around Europe, since only 6 stations exhibited higher values (Pandolfi *et al.*, 2018). Titos *et al.* (2014) reported b_{sca} values of $41 \pm 34 \text{ Mm}^{-1}$ for winter 2013 and $38 \pm 26 \text{ Mm}^{-1}$ for spring 2013 in Granada, Spain, which are similar in spring, but much lower in winter compared to Athens. However, much lower b_{abs} values were found in Granada (17 Mm^{-1} and 11 Mm^{-1} for winter 2013 and spring 2013, respectively; Titos *et al.*, 2014) compared to Athens. The

b_{sca} values in Athens are comparable in magnitude, although slightly lower, to those found for clean and heavy smog days (26 Mm^{-1} and 410 Mm^{-1} , respectively) in Los Angeles (Seinfeld and Pandis, 1998). In contrast, very high values of b_{sca} ($230\text{--}700 \text{ Mm}^{-1}$) and b_{abs} ($60\text{--}80 \text{ Mm}^{-1}$) were reported over highly-polluted megacities like Beijing (He *et al.*, 2009), New Delhi (Dumka *et al.*, 2017) and Mexico City (Paredes-Miranda *et al.*, 2009).

Figs. 2(a)–2(b) show the daily variability of the b_{sca} (from 9.2 to 223.9 Mm^{-1}) and b_{abs} (4.3 to 169.7 Mm^{-1}) as a function of the $\text{SAE}_{450\text{--}700}$ and $\text{AAE}_{370\text{--}880}$ values, respectively (colored scales), while hourly b_{sca} and b_{abs} values as high as $\sim 700 \text{ Mm}^{-1}$ and $\sim 500 \text{ Mm}^{-1}$, respectively, were recorded during pollution-smog conditions. Enhanced daily b_{sca} values are encountered from December to February exhibiting a decreasing tendency afterwards (Fig. 2(a)), while the b_{abs} follows a similar fluctuation (Fig. 2(b)). The scatter plot between the hourly b_{sca} and b_{abs} values (Suppl. Fig. S1) exhibited a significant correlation (slope = 0.72 ; $R^2 = 0.80$, $N = 7758$), indicating a covariance in the scattering and absorption aerosol properties due to similarity in the emission sources. During December–January a more homogeneous atmosphere, composed by fine-mode anthropogenic aerosols ($\text{SAE} > 2.0$) is the dominant scenario, contrary to the transition months (March–May and September–November), which show important heterogeneity in the aerosol sources and properties. Remarkable seasonality is observed in AAE with large (> 1.5) values even for low b_{abs} in December and January, and values mostly below ~ 1.4 from April to October (Fig. 2(b)). The numerous forest fires in Greece during summer 2017 do not seem to influence the aerosol loading (b_{sca} , b_{abs}) in Athens center, since the transported smoke plumes were traversed at elevated heights far away from the Attica region.

However, in this work, emphasis is given on examining the extensive and intensive aerosol properties of urban/anthropogenic aerosols during dry conditions. In this respect, the rainy days, based on data from the NOA's meteorological station at Thissio, were excluded from the rest of the analysis, as well as the dusty days. The dusty days were flagged based initially on HYSPLIT back trajectories for the major dust storms affecting the eastern Mediterranean and Greece, combined with concurrent sharp peaks in the measured PM_{10} concentrations

Table 1. Mean values of the aerosol optical properties in Athens for the whole dataset and after excluding the dusty and rainy days (in parenthesis).

	Whole period	Winter	Spring	Summer	Autumn
b_{sca}	46.01 ± 32.21	63.57 ± 73.59	39.26 ± 29.55	33.50 ± 15.63	42.77 ± 34.45
(550 nm)	(47.19 ± 48.90)	(72.81 ± 81.14)	(40.27 ± 29.94)	(33.64 ± 14.70)	(41.23 ± 31.89)
b_{abs}	28.45 ± 36.29	41.01 ± 59.72	22.04 ± 21.68	22.95 ± 18.04	27.61 ± 28.17
(520 nm)	(29.14 ± 39.18)	(45.70 ± 65.92)	(23.25 ± 22.39)	(20.58 ± 13.53)	(26.45 ± 27.47)
SAE	1.99 ± 0.34	1.99 ± 0.34	1.98 ± 0.35	2.14 ± 0.23	1.89 ± 0.39
($450\text{--}700$)	(2.02 ± 0.31)	(2.05 ± 0.21)	(2.02 ± 0.27)	(2.14 ± 0.24)	(1.89 ± 0.35)
AAE	1.32 ± 0.23	1.50 ± 0.26	1.25 ± 0.16	1.24 ± 0.18	1.28 ± 0.18
($370\text{--}880$)	(1.33 ± 0.22)	(1.53 ± 0.26)	(1.26 ± 0.15)	(1.25 ± 0.15)	(1.28 ± 0.18)
SSA	0.62 ± 0.11	0.60 ± 0.08	0.64 ± 0.12	0.61 ± 0.09	0.61 ± 0.12
(550 nm)	(0.66 ± 0.11)	(0.68 ± 0.08)	(0.67 ± 0.13)	(0.65 ± 0.08)	(0.61 ± 0.13)

Fig. 2. Temporal variation of the daily values of (a) b_{sca} at 550 nm and (b) b_{abs} at 520 nm during the whole period as a function of the daily $\text{SAE}_{450-700}$ and $\text{AAE}_{370-880}$ values (colored scales), respectively.

(Diapouli *et al.*, 2017b). Overall, 271 days with 6269 hourly data remained for the analysis (1489 hours were excluded). The main aerosol optical properties (e.g., b_{sca} , b_{abs} , SAE, AAE, SSA) present marginal differences in the case of exclusion of the dusty and rainy days, as can be seen from Table 1. However, this exclusion leads to higher b_{sca} and b_{abs} values, as well as to differences between the two datasets in winter due to much lower concentrations on the rainy days (washout). Furthermore, the hourly datasets for all aerosol properties were classified into two groups based on the hourly WS threshold of 3 m s^{-1} , which was identified as a critical value for the discrimination between high-to-very high and moderate-to-low b_{sca} and b_{abs} values (see Suppl. Fig. S2). That figure shows that both b_{sca} and b_{abs} values exhibited a rather exponential increase for WS below 3 m s^{-1} . Furthermore, there is greater possibility for enhanced AAE values for $\text{WS} < 3 \text{ m s}^{-1}$, probably attributed to the influence of residential wood burning in winter nights under weak-to-calm winds (see Suppl. Fig. S3). The cases with $\text{WS} < 3 \text{ m s}^{-1}$ are characterized as haze/smog

conditions and the other as non-smog, following the classification by Fourtziou *et al.* (2017). Therefore, the rest of the study focuses on analyzing the near-surface urban/anthropogenic aerosols, and separately for the smog and non-smog conditions on a seasonal basis, in order to reveal changes in aerosol properties attributed to different sources, meteorology and wind speed.

The seasonally-averaged diurnal cycles of the b_{sca} (Figs. 3(a)–3(d)) and b_{abs} (Figs. 4(a)–4(d)) are examined separately for the two groups, i.e., smog ($\text{WS} < 3 \text{ m s}^{-1}$) and non-smog ($\text{WS} \geq 3 \text{ m s}^{-1}$) conditions, revealing a remarkable, seasonally-changed, and wind dependent diurnal variability. Very high seasonal-mean b_{sca} values (at 450 nm) reaching $250\text{--}300 \text{ Mm}^{-1}$ are recorded during the night hours in winter for $\text{WS} < 3 \text{ m s}^{-1}$, indicating significant accumulation of aerosols and pollutants near the surface and formation of haze/smog conditions. In contrast, the cases with $\text{WS} \geq 3 \text{ m s}^{-1}$ are characterized by much lower b_{sca} values, especially during nighttime, indicating rather efficient dispersion of aerosols. A secondary b_{sca} peak

Fig. 3. Seasonal-mean diurnal patterns of b_{sca} (450 nm) for cases with wind speeds above and below 3 m s^{-1} . The rainy and dusty days have been excluded. The vertical bars correspond to one standard deviation from the hourly mean.

around 11:00 LST is shown in winter that is absent under $WS \geq 3 \text{ m s}^{-1}$ conditions, which is attributed to the morning traffic rush hour, usually peaking 1–2 hours earlier. This suggests that the urban emissions need about 1–2 hours, depending on the general flow within the basin, to reach the urban/background site of Thissio (at the top of the hill of Nymphs). After this slight morning peak, the b_{sca} levels are progressively decreasing till about 16:00–17:00 LST due to increase in the mixing-layer height (MLH) and the higher vertical and horizontal dispersion (Kalogridis *et al.*, 2018). The lowest b_{sca} levels of $\sim 70 \text{ Mm}^{-1}$ at 17:00 LST increase abruptly ($\sim 33 \text{ Mm}^{-1}$ per hour) till about 00:00–01:00, due to enhanced emissions mostly from bio-fuel and residential wood burning for heating purposes (Panopoulou *et al.*, 2017; Kalogridis *et al.*, 2018). On this increase, the evening traffic-rush hours and the fossil-fuel emissions from the central heating should not be ignored, but previous studies at Thissio clearly revealed that the largest amounts of OC, BC and CO emissions during winter nighttime come from wood burning (Fourtziou *et al.*, 2017; Gratsea *et al.*, 2017; Stavroulas *et al.*, 2018). The fading use of fire places till about 11:00–00:00 LST and the near absence of traffic during nighttime contribute to the progressive decrease of

the b_{sca} levels during the night. On the contrary, the b_{sca} values are much lower during the other seasons and for the non-smog cases, suggesting more transparent atmospheric conditions, on which the locally-emitted aerosols have less impact on the near-surface concentrations. Furthermore, the diurnal variations of the b_{sca} seem to be nearly independent from the WS in the other seasons, except for the night hours in spring and autumn due to accumulation of aerosols in the cold months of March and November, respectively.

In general, the seasonal-mean diurnal cycles of b_{abs} (Figs. 4(a)–4(b)) follow those of b_{sca} (Figs. 3(a)–3(d)). Therefore, during winter, b_{abs} exhibits a pronounced peak at 10:00–11:00 LST (1–2 hours after the morning rush traffic), indicating the presence of highly-absorbing aerosols from vehicle exhaust (cases with $WS < 3 \text{ m s}^{-1}$). However, the primary peak in b_{abs} ($170\text{--}180 \text{ Mm}^{-1}$ at 470 nm) is observed during late night (23:00–01:00 LST), due to higher relative contribution by wood burning and OC emissions for heating purposes (Fourtziou *et al.*, 2017; Gratsea *et al.*, 2017), as also shown in Paris (Sciare *et al.*, 2011); Ispra, Italy (Putaud *et al.*, 2014); Barcelona, Spain (Minguillón *et al.*, 2015), and in Alpine sites in Switzerland (Zotter *et al.*, 2017). This is especially pronounced for the low-wind cases

Fig. 4. Seasonal-mean diurnal patterns of the b_{abs} (470 nm) for cases with wind speeds above and below 3 m s^{-1} . The rainy and dusty days have been excluded. The vertical bars correspond to one standard deviation from the hourly mean.

indicating a highly-absorbing aerosol laden atmosphere in Athens center, while the diurnal patterns of b_{abs} exhibit much lower variability in the other seasons. The local, freshly emitted aerosols from traffic seem to affect more the light absorption rather than scattering, since the morning peaks in b_{abs} are more pronounced than those for b_{sca} . In autumn (Fig. 4(d)), the morning and night peaks are equal, while in spring (Fig. 4(b)) the morning traffic exhibits a higher signal in b_{abs} ; in contrast, both diurnal patterns flatten out in summer (Fig. 4(c)). Similar to b_{sca} , any diurnal cycle nearly vanishes in the non-smog cases ($WS \geq 3 \text{ m s}^{-1}$), except of the slight increase during the morning hours in spring, indicating a good mixing and dispersion of pollutants under higher wind speeds.

The regionally-changing daily wind patterns and the local sea-land breeze circulation may also affect the diurnal patterns of b_{sca} and b_{abs} , resulting in large standard deviations from the respective means. As the industrial and vehicular emissions within the Athens Basin are assumed nearly constant during daytime, the large decrease in the b_{sca} and b_{abs} at noon and early afternoon is attributed to boundary-layer dynamics, i.e., deepening of the MLH due to solar heating that favors the vertical and horizontal dispersion of

the aerosols and pollutants (Cohen and Wang, 2014; Lee et al., 2016). Previous studies (Grivas et al., 2008; Gratsea et al., 2017) have also shown increased PM concentrations over Athens during the early morning and evening hours due to lower MLH and trapping of pollutants near the ground, followed by lower concentrations around noon. Therefore, the boundary-layer dynamics and the dispersion processes play an important role in the prevention of pollutant accumulation, in redistribution of aerosols and in weakening of the impact of local sources.

The b_{sca} and b_{abs} coefficients are further examined against $\text{PM}_{2.5}$, PM_{10} concentrations and gaseous pollutants (CO and NO), characteristic for traffic-related and biomass-burning emissions. December 2016 was chosen for this analysis due to its high aerosol concentrations (Figs. 1(a)–1(b)). The diurnal cycles of scattering at 550 nm, CO, NO and PM_{10} concentrations show, in general, great similarities driven by the changes in the emission sources and MLH (Fig. 5). Therefore, as in the b_{sca} case, two maxima exist for both CO and NO, but with a characteristic time shift in the evening hours and a difference between the primary and secondary peaks. CO presents a better coincidence with b_{sca} , peaking at 23:00 LST due to enhanced emissions

Fig. 5. Mean diurnal variations for the b_{sca} (550 nm), CO, NO and PM_{10} over Athens in December 2016.

from heating sources, while the secondary peak at ~09:00 LST is related to the morning rush traffic (fossil-fuel emissions) and coincides with NO. During the evening-to-night hours, NO peaks one hour before CO, coinciding with the evening rush traffic, while CO is mostly related to wood burning (Koyuncu and Pinar, 2007). However, the morning b_{sca} secondary peak is not so remarkable, revealing much less aerosol abundance or even fewer scattering particles during the morning traffic hours. Note also the excellent coincidence between b_{sca} and PM_{10} diurnal patterns in December ($R^2 = 0.95$), revealing that the primary gas emissions during the morning hours do not impose a distinct signal on PM_{10} concentrations, whereas the wood burning emissions contribute significantly to the increased PM_{10} levels (above $40 \mu\text{g m}^{-3}$) during nighttime. The correlation of b_{sca} with CO and NO in December was of $R^2 = 0.73$ (slope: 4.94) and $R^2 = 0.14$ (slope: 0.23), respectively. In addition, a strong correlation ($R^2 = 0.80$, slope: 0.28) was found between the daily b_{sca} and $PM_{2.5}$ concentrations during the whole period, which is similar to that reported in Ispra, north Italy ($R^2 = 0.87$), between dry $PM_{2.5}$ and scattering coefficient (Putaud *et al.*, 2014). Very good correlations between b_{sca} and PM_{10} concentrations, with R^2 values of 0.86–0.89, were also reported in a regional site in NE Spain (Pandolfi *et al.*, 2011).

The diurnal cycles of b_{abs} , CO and NO in December (Fig. 6) are almost identical, highlighting the vital role of the primary combustion sources on the aerosol absorption processes. Therefore, apart from the evening/night peaks in CO and NO, associated with the wood burning and evening traffic hours, as discussed above, the morning gaseous peaks due to traffic have a direct effect on aerosol absorption, contrary to that found for scattering. This suggests significant amounts of freshly-emitted BC aerosols with high absorbing capability. Furthermore, the CO/NO ratio may be used for qualitative assessment of the relative dominance between

traffic and biomass burning (Sandr Dewi *et al.*, 2008; Sciare *et al.*, 2011). Wood burning leads to higher CO emissions, while fossil-fuel combustion in vehicle engines occurs at high temperatures, is more complete, with higher NO emissions and lower CO/NO ratios (Koyuncu and Pinar, 2007; Reche *et al.*, 2012). Therefore, the lower CO/NO values are observed during the morning (around 8:00–9:00 LST) and evening (around 20:00–21:00 LST) rush traffic hours, whereas during nighttime the CO/NO ratio slightly increases reflecting the wood burning. The average diurnal pattern of CO/NO in December ranges between 8.4 and 52.2 with a mean of 20.8 ± 10.8 , suggesting remarkable variability in the anthropogenic and natural emissions, combustion sources and changes in the relative dominance between them within the urban environment (Reche *et al.*, 2012; Zheng *et al.*, 2017). However, during daytime, the NO concentrations are also affected by the oxidation of NO to NO_2 , while the photochemical reactions reduce the NO in much higher rate than CO, resulting in larger CO/NO values during noontime (Fig. 6). In addition, CO/NO ratio might change due to aging processes, even without changes in the emission sources, since CO/NO increases for aged aerosols due to lower lifetime of NO compared to CO (Sandr Dewi *et al.*, 2008).

SAE and AAE

The monthly variations of the SAE values at three wavelength bands (450/550, 450/700, 550/700 nm), and AAE at the 370–520 nm, 370–880 nm, and 520–880 nm are examined in Figs. 7(a)–7(b). Despite the wide range in SAE values (from below 1.0 to 2.6), the monthly means and medians lie between ~1.9 and 2.2 (Fig. 7(a)), suggesting a clear dominance of fine urban/anthropogenic aerosols (Srivastava *et al.*, 2014). The much lower range in SAE values in June may be attributed to a smaller dataset in this month (202 hours, instead of e.g., 504 in May). The annual

Fig. 6. Mean diurnal variations for the b_{abs} (880 nm), CO, NO and CO/NO ratio over Athens in December 2016.

averages for $SAE_{450-550}$, $SAE_{450-700}$ and $SAE_{550-700}$ values are very close to each other, 1.99 ± 0.29 , 2.02 ± 0.31 and 2.03 ± 0.34 , respectively. The SAE values increase with wavelength (i.e., $SAE_{550-700} > SAE_{450-550}$) from October to March, whereas they present a neutral to declining tendency from April to September (except from June). This indicates some differences in the fine-to-coarse mode aerosol ratio, since the increase in SAE with the wavelength implies larger fraction of fine-mode aerosols (larger fine-to-coarse mode ratio) during the winter months, while neutral to slightly decreasing values indicate a rather good mixing of fine and coarse particles (Eck *et al.*, 2005; Schuster *et al.*, 2006). Large SAE values (> 2.0) are observed in summer (Fig. 7(a)), mostly representing regional background conditions and secondary organic aerosol (SOA) formation in the absence of dust near the surface. Note that carbonaceous aerosols were also responsible for the high SAE values (~ 2.2 – 2.4) in summer in NE Spain (Ealo *et al.*, 2018). High SAE values (~ 1.8 – 2.0) were also reported at other central and eastern European sites, which maximized in summer due to higher biogenic SOA and new-particle formation, while they could be considered as typical for background conditions of no-dust (Ma *et al.*, 2014; Pandolfi *et al.*, 2018).

On the other hand, the large monthly variation in the AAE values and wavelength dependence (Fig. 7(b)) suggests remarkable changes in the dominant aerosol types and emission sources. Therefore, the larger $AAE_{370-520}$ values and wavelength dependence of AAE are associated with enhanced contribution from biomass-burning aerosols (November–March), while values of AAE close to 1.1–1.2 with less wavelength dependence correspond to a clear dominance of fossil-fuel (vehicles, industries) combustion in spring and summer (Kirchstetter *et al.*, 2004; Andreae and Gelencsér, 2006; Zotter *et al.*, 2017). The AAE values are significantly lower as the wavelength increases implying

much lesser impact of wood burning emissions (Sandradewi *et al.*, 2008; Titos *et al.*, 2017). The slightly larger AAE values in August are attributed to the influence of forest fires (13–15 August 2017) about 40 km northeast of Athens. During the whole period, the $AAE_{370-880}$ ranges from 1.1 to 2.1 on a daily basis, with an average of 1.33 ± 0.22 . Very different AAE values are reported in the literature depending on the fuel type and combustion efficiency (flaming or smoldering), such as values of ~ 2.2 for firewood burning, ~ 1.8 for savanna fires and 0.8–1.1 for traffic (Eck *et al.*, 2003; Kirchstetter *et al.*, 2004; Day *et al.*, 2006).

The seasonal-mean diurnal variations of $SAE_{450-700}$ for WS above and below 3 m s^{-1} do not exhibit distinct patterns in any season and/or for the separate data groups (Fig. 8). Therefore, no important diurnal cycles regarding changes in the particle size or in the fine-to-coarse mode aerosol ratios could be extracted and an overall dominance of fine-mode anthropogenic aerosols is revealed. However, in winter and autumn, the SAE values for the smog cases are slightly higher throughout the day, indicating enhanced presence of fine, freshly-emitted aerosols. The seasonal-mean diurnal patterns of AAE (Fig. 9) clarify the dominance of different aerosol sources and combustion processes in the Athens Basin according to season and hour of the day. Therefore, local emissions from bio-fuel burning dominate in the evening and night hours in winter (large AAE values) and presence of aerosols from fossil-fuel combustion, or SOA formation (low values of AAE), dominate around noon in winter and in the other seasons (Bergstrom *et al.*, 2007).

Relating SAE to AAE values is able to reveal aerosol types of different origin and combustion sources, since concurrently high AAE and SAE correspond to biomass-burning aerosols, while low SAE and high AAE values are indicative of desert dust; values of AAE around 1.0–1.1 associated with high SAE imply for urban emissions from

Fig. 7. Monthly values of the (a) SAE and (b) AAE at three wavelength bands over Athens from October 2016 to September 2017, excluding the rainy and dusty days. The box's upper and lower limits are the 75 and 25 percentiles, respectively, the black circle corresponds to the mean and the straight line denotes the median. The whiskers denote the 95 and 5 percentiles.

fossil-fuel combustion (Russel *et al.*, 2010; Cazorla *et al.*, 2013; Srivastava *et al.*, 2014). Fig. 10 correlates the hourly $SAE_{450-700}$ and $AAE_{370-880}$ in Athens as a function of month (colored scale), indicating that the high AAE and SAE values correspond to months during the cold period (November–February), implying for significant impact of residential wood burning (Fourtziou *et al.*, 2017). Cases with desert dust are absent (the dusty and rainy days have been excluded), while cases with AAE in the range of 1.1–1.3 and SAE values below 1.4 correspond to mixing of fossil-fuel emissions with other aerosols from coarser size, like re-suspended dust. More detailed analysis is needed for the classification of the various aerosol types via the AAE vs. SAE scatter plot and examination of the emission sources, taking also into account the SSA, BC concentrations and chemical composition.

Single Scattering Albedo

The exclusion of the rainy and dusty days led to a slight

increase in the SSA values (Table 1), which ranges from ~ 0.2 to 0.9 (mean of 0.66 ± 0.11) at 550 nm, while the respective means at 450 and 700 nm were found to be 0.68 ± 0.11 and 0.62 ± 0.12 , respectively. Furthermore, the SSA values were generally lower under weak winds ($WS < 3 \text{ m s}^{-1}$) (Suppl. Fig. S3) indicating accumulation of the fresh urban emissions that are characterized by highly absorbing aerosols (e.g., large fraction of BC from fossil-fuel emissions). It is characteristic that the mean SSA values are very similar for all months regardless of the wavelength (Fig. 11). SSA values around 0.6–0.7 have also been reported in Athens via an indirect method of simulating the diffuse/direct irradiance ratio (Kaskaoutis *et al.*, 2016).

The monthly variation of the spectral SSA (Fig. 11) reveals a rather complicated annual pattern for both values and spectral dependence, implying changes in the dominant aerosol types. A decrease of SSA with wavelength is seen in all months, suggesting dominance of urban/industrial aerosols (Dubovik *et al.*, 2002). However, the decreasing

Fig. 8. Seasonal-mean diurnal patterns of the $SAE_{450-700}$ for cases with wind speeds above and below 3 m s^{-1} . The rainy and dusty days have been excluded. The vertical bars correspond to one standard deviation from the hourly mean.

rate in SSA may be further used to apportion the aerosol sources (Patel *et al.*, 2017), since the highest decreasing rates correspond to aerosols with high BC fraction from fossil-fuel combustion (March–September), while lower spectral variations occur from enhanced presence of OC mixed with BC from wood burning (November–February) (Habib *et al.*, 2008). On the other hand, the SSA is strongly associated with the fraction of absorbing aerosols (mostly BC) to the total aerosol mass at the ground and the low SSA values in spring and summer are attributed to the predominance of the urban/anthropogenic aerosols. Previous studies (Virkkula *et al.*, 2011; Lihavainen *et al.*, 2015) reported low SSA values, usually below 0.7, at Northern European sites during winter due to contribution from residential wood combustion sources, while winter SSA_{637} of 0.70 ± 0.09 was found in Granada, Spain (Titos *et al.*, 2014). Much higher SSA of 0.90 ± 0.05 associated with significantly lower SAE values (1.33 ± 0.48) were reported at a regional site in NE Spain (Pandolfi *et al.*, 2011), indicating large differences in the aerosol types and properties compared to Athens.

The seasonal-mean diurnal patterns of SSA_{550} reveal

distinct differences for the two groups (wind speeds above and below 3 m s^{-1}) in all seasons except summer (Fig. 12). Therefore, in winter, spring and autumn, the SSA for the smog cases exhibits a pronounced diurnal pattern with lower values during the morning traffic hours and a progressive increase until noon and early afternoon ($\sim 15:00$ – $16:00$ LST). Then, a slight decrease follows until the night hours. The large gap in SSA values during the morning rush traffic hours clearly reveals the influence of the highly-absorbing BC aerosols from complete combustion (vehicle exhaust) (Dubovik *et al.*, 2002; Kanakidou *et al.*, 2005; Ealo *et al.*, 2018). On the other hand, the SOA formation around noon may increase the SSA as these particles are more efficient scatterers (Sarkar *et al.*, 2017). The respective diurnal patterns for the non-smog cases follow, in general, a similar variation but with a lower range and larger SSA values throughout the day, apart from noon and afternoon hours. This indicates that for $WS \geq 3 \text{ m s}^{-1}$ there is higher possibility for dispersion of the urban/traffic emissions and for better mixing with soil aerosols and road-dust re-suspension, which are larger particles with higher SSA values. In addition, we also analyzed the diurnal patterns

Fig. 9. Seasonal-mean diurnal patterns of the $AAE_{470-880}$ for cases with wind speeds above and below 3 m s^{-1} . The rainy and dusty days have been excluded. The vertical bars correspond to one standard deviation from the hourly mean.

Fig. 10. Scatter plot between $SAE_{450-700}$ and $AAE_{370-880}$ hourly values, as a function of month (colored scale) in Athens during the period October 2016–September 2017.

Fig. 11. Monthly values of the spectral SSA over Athens from October 2016 to September 2017, excluding the rainy and dusty days. The box's upper and lower limits are the 75 and 25 percentiles, respectively, the black circle corresponds to the mean and the straight line denotes the median. The whiskers denote the 95 and 5 percentiles.

Fig. 12. Seasonal-mean diurnal patterns of the SSA_{550} for cases with wind speeds above and below 3 m s^{-1} . The rainy and dusty days have been excluded. The vertical bars correspond to one standard deviation from the hourly mean.

of the wavelength dependence of SSA between 450 nm and 700 nm, expressed via the SSA wavelength exponent (α -SSA), on seasonal basis for the two groups of data (Figs. 13(a)–13(b)). For the smog cases (Fig. 13(a)), the results show lower α -SSA values in winter, characteristic of enhanced levels of biomass-burning aerosols that reflect lesser wavelength dependence of SSA compared to fossil-fuel combustion from vehicles and industries (Liu *et al.*, 2014; Stockwell *et al.*, 2016; Schuster *et al.*, 2016). This is also verified by the remarkable increase in α -SSA values during the morning rush-traffic hours in all seasons except summer. The summer increase in α -SSA during late afternoon-to-evening hours may be also related to increased traffic emissions (entertainment hours). The seasonal-mean diurnal cycles of the α -SSA verify the signals of the traffic- and biomass-related carbonaceous aerosol emissions in Athens. Lower α -SSA values in winter and higher in summer, but without any distinct diurnal cycle, are shown for cases with $WS \geq 3 \text{ m s}^{-1}$, thus corresponding to well-mixed atmospheric conditions in each season with increased fraction of biomass burning in winter (Fig. 13(b)).

Contribution of Chemical Species to Light Scattering

Apart from the particle size and shape, the aerosol chemical composition also plays a crucial role in the light scattering and absorption processes (Tao *et al.*, 2014; Dumka *et al.*, 2017). In this respect, the reconstruction of the b_{sca} via chemical components measured with ACSM is attempted, also examining their individual contribution to light scattering in Athens. The daily b_{sca} values were found to be highly correlated (slope: 0.29, $R^2 = 0.91$) with the total chemical mass concentrations via ACSM during the whole campaign. Similarly, strong correlations ($R^2 = 0.94$ – 0.97) were found between b_{ext} and mass of anthropogenic aerosols [$OM + EC + (NH_4)_2SO_4 + NH_4NO_3$] over Delhi, while the b_{ext} was much more weakly dependent on the natural (soil and desert dust) components (Dumka *et al.*, 2017), suggesting that the anthropogenic emissions play the major role in light attenuation in urban environments.

The monthly variation of the cumulative concentrations of the various components in the non-refractory PM_{10} mass shows higher values during November–February (19 – $25 \mu\text{g m}^{-3}$) and much lower ($8.3 \mu\text{g m}^{-3}$) in May (Fig. 14).

Fig. 13. Seasonal-mean diurnal patterns for the SSA exponent (α -SSA) for smog ($WS < 3 \text{ m s}^{-1}$) (a) and non-smog ($WS \geq 3 \text{ m s}^{-1}$) (b) conditions. The rainy and dusty days have been excluded.

During the summer months the fine-mode mass concentrations increase ($14.2\text{--}15.5\ \mu\text{g m}^{-3}$), mostly attributed to the increase of organics and sulfate due to photochemical reactions and enhanced secondary aerosol formation. The average organics, SO_4^{2-} , NO_3^- , BC and NH_4^+ concentrations during the whole period were $7.9 \pm 3.3\ \mu\text{g m}^{-3}$, $3.9 \pm 0.7\ \mu\text{g m}^{-3}$, $0.8 \pm 0.5\ \mu\text{g m}^{-3}$, $1.9 \pm 0.7\ \mu\text{g m}^{-3}$, and $1.1 \pm 0.2\ \mu\text{g m}^{-3}$, respectively. Organics, BC and NO_3^- exhibit the highest concentrations ($15.3\ \mu\text{g m}^{-3}$, $3.4\ \mu\text{g m}^{-3}$ and $1.8\ \mu\text{g m}^{-3}$, respectively) in December and the lowest in May ($3.1\ \mu\text{g m}^{-3}$, $1.1\ \mu\text{g m}^{-3}$ and $0.25\ \mu\text{g m}^{-3}$, respectively), while the high correlation between sulfate and ammonium (slope = 3.2; $R^2 = 0.77$) and between nitrate and chloride ($R^2 = 0.92$) indicates common sources, which for the case of ammonium and sulfate come from secondary aerosol formation and for the case of nitrate and chloride from local combustion processes mostly during wintertime. Based on the ACSM measurements, organics contributed 46.1% to the total non-refractory submicron mass during summer, followed by sulfate (31.7%), BC (10.7%) and ammonium (8.7%), while during winter, organics and sulfate contributed 57.3% and 16.3%, respectively, followed by BC (13.3%), ammonium (5.1%) and nitrate (7.1%) (Suppl. Fig. S4). Organic aerosols contribute almost the half to the PM_{10} mass, on annual average, sulfate exhibits the most seasonally dependent contributions, while an important finding is the 10–14% contribution of the BC in all seasons. OC was the major contributor to the $\text{PM}_{2.5}$ mass (~20–30%) at urban European sites (Putaud *et al.*, 2010), while its contribution to $\text{PM}_{2.5}$ in Athens has been found to be around 30% (Pateraki *et al.*, 2011; Theodosi *et al.*, 2011).

The reconstructed b_{sca} values at 550 nm are highly correlated with the Nephelometer measurements during the period October 2016–August 2017, with an $R^2 = 0.91$ (slope: 1.08), and a slight bias of 8% (Fig. 15). Very good agreement between the measured and modeled b_{sca} at 525 nm ($R^2 = 0.88\text{--}0.92$), with slopes between 0.96 and 0.98 was also found in NE Spain (Ealo *et al.*, 2018). The relative contributions of each component to the light

scattering (Eqs. (4)–(5)) are examined in two periods, i.e., from October to mid-May for POM, AS and AN, and from mid-May to August for POM and AS. POM and AS contribute 51% and 39%, respectively to the b_{sca} , while AN contributes only by 10% during October to mid-May. For mid-May to August, the corresponding values for POM and AS were found to be 56.5% and 43.5%, since nitrate formation is not favored. Similarly, previous studies in eastern (Kalivitis *et al.*, 2011) and western Mediterranean (Pandolfi *et al.*, 2011) found higher concentrations for the ammonium sulfate and POM in summer being important contributors to b_{sca} . A study over Delhi using the IMPROVE algorithms (Dumka *et al.*, 2017) found that the OM contributed 39% and 48% to the b_{ext} , followed by $(\text{NH}_4)_2\text{SO}_4$ (21% and 24%), Elemental Carbon (EC) (13% and 10%) and NH_4NO_3 (9% and 5%). A similar approach applied in China (Cao *et al.*, 2012) revealed largest contributions to b_{ext} by $(\text{NH}_4)_2\text{SO}_4$ (40%), OM (24%), NH_4NO_3 (23%) and EC (9%). The carbonaceous aerosols contributed also the largest fraction (OM: 39% and EC: 20%) to b_{ext} in the polluted Pearl River Delta, China, followed by $(\text{NH}_4)_2\text{SO}_4$ (16%), coarse mode (13%) and NH_4NO_3 (11.8%) (Zhang *et al.*, 2013).

SUMMARY AND CONCLUSIONS

The seasonality of the spectral variation in the near-surface aerosol properties, namely, the scattering and absorption coefficients, along with spectral SSA calculations via combined Nephelometer and Aethalometer measurements, were examined in the Athens urban environment from October 2016 to September 2017. The analysis was complemented by concurrent measurements of chemical species (organics, BC, sulfate, nitrate, ammonium and chloride) via ACSM, air pollutants (CO and NO), PM concentrations and meteorological observations. The main objectives were to reveal the near-surface urban aerosol characteristics and to assess the influence of different combustion sources (vehicle exhaust, industry, bio-fuel

Fig. 15. Scatter plot between the reconstructed and measured b_{sca} (at 550 nm) daily values during the period October 2016 to August 2017. The contributions of the individual chemical species for the cold (October–mid-May) and warm (mid-May–August) seasons are also given in the graph.

and wood burning) on the extensive and intensive aerosol properties in each season. Furthermore, the contribution of the major chemical species to the b_{sca} was evaluated, as well as the influence of local and regional combustion sources from traffic and wood burning on aerosol optical properties and pollutant emissions.

The b_{sca} and b_{abs} exhibited a high temporal variation and a distinct seasonality with larger values in winter and lower ones in spring and summer. Annual means of $46.0 \pm 32.2 \text{ Mm}^{-1}$ for the b_{sca} at 550 nm and of $28.4 \pm 36.3 \text{ Mm}^{-1}$ for the b_{abs} at 520 nm were found, and the mean value for the SSA was 0.62 ± 0.11 at 550 nm. The large increase in both the b_{sca} and b_{abs} in the last week of November and during winter was attributed to enhanced residential wood burning emissions from heating, as the economic recession during the recent years in Greece has prompted people to use fireplaces instead of the more expensive fossil fuels. The residential wood burning emissions left their signal on the aerosol optical properties via the high b_{sca} , b_{abs} and PM concentrations and the large SAE (~ 2.1) and AAE (> 1.5) values from November to February, indicating the accumulation of sub-micron aerosols, with a significant fraction of organic carbon from biomass burning. During the rest of the year, the b_{sca} and b_{abs} values were much lower, with AAE values in the range of 1.1–1.2, indicating the dominance of aerosols from fossil-fuel combustion (vehicle exhaust and industry). By contrast, the SAE values remained high (~ 2.0) throughout the year, suggesting the dominance of fine urban/anthropogenic aerosols. Further

analysis of the diurnal variations of the spectral b_{sca} and b_{abs} revealed two peaks during the morning and evening/night hours, due to traffic-related and wood burning emissions, respectively. These diurnal cycles were clearly detected during the autumn and winter and in cases with wind speeds below 3 m s^{-1} , characterized as smoggy conditions. In the other seasons and with higher wind speeds, any diurnal variation tended to flatten out, indicating that apart from the local emissions, the boundary-layer dynamics and changes in wind speed are important factors in controlling the aerosol load and properties in Athens. The reconstructed b_{sca} values via the chemical closure analysis showed very good agreement with the measurements ($R^2 = 0.91$; bias of 8%). Organic matter was found to be the largest contributor ($\sim 51\%$) to the b_{sca} from October to mid-May, followed by ammonium sulfate ($\sim 39\%$) and ammonium nitrate ($\sim 10\%$).

ACKNOWLEDGEMENTS

The financial support by the European Community through the ACTRIS Research Infrastructure Action under the 7th Framework Programme (Grant Agreement No. 262254) is gratefully acknowledged. The analysis was partly supported by ERA-PLANET (www.era-planet.eu), trans-national project SMURBS (www.smurbs.eu) (Grant Agreement No. 689443), funded under the EU Horizon 2020 Framework Programme. The authors want to thank the editor and the anonymous reviewers for their comments, which helped improved the initially submitted version.
