ABSTRACT

The impact of the planetary boundary layer (PBL) structure on the vertical distribution of aerosols in Northeast China, which experiences air pollution frequently in autumn and winter, is not well understood. We investigated the characteristics of the vertical distribution of particulate matter (PM₁, PM_{2.5}, and PM₁₀) mass concentrations and their relationships with PBL structures in Shenyang, a provincial capital city in Northeast China, using balloon sounding data collected during an intensive observation period in November 2018. Aerosols typically decreased with increases in height and were mostly distributed below 400 m at night and reached higher altitudes (~800 m) in the daytime due to convective turbulence. The concentration ratios of PM₁/PM_{2.5} and PM_{2.5}/PM₁₀ measured about 0.6 and 0.8, respectively, below 0.6–1.0 km during the daytime, and below 0.5 km at nighttime. On average, stronger atmospheric stability resulted in greater vertical gradients and higher PM concentrations near the surface. During four air pollution episodes (November 1–4, 7–10, 14–15, and 25–27), when atmospheric stability was strong at night, aerosols tended to remain in a shallow stable surface layer (< 300 m) and at the bottom of a residual layer (250–500 m) due to weak vertical mixing. After sunrise, these aerosols were mixed uniformly in the PBL (the depth increasing from 200 m to more than 1 km), subsequently affecting surface air quality. In addition, strong wind speeds and wind shears caused by nocturnal low-level jets and cold front systems influenced the formation and evolution of air pollution episodes. These processes controlled aerosol transport/dispersion processes and can modify atmospheric stability and PBL height. These results have important implications for understanding the vertical distribution of aerosols, and the crucial roles that PBL structures play in modulating aerosol pollution in Shenyang.

Keywords: Vertical distribution; Particulate matter; Planetary boundary layer structure; Air pollution; Northeast China.

INTRODUCTION

Atmospheric particulate matter (PM) can affect air quality (Fuzzi *et al.*, 2015; Jiang *et al.*, 2015), visibility (Kim *et al.*, 2006; Li *et al.*, 2016), human health (Davidson *et al.*, 2005; Kim *et al.*, 2015; Tang *et al.*, 2017), and the earth's radiation budget (Myhre *et al.*, 2013; Huang *et al.*, 2014), depending on particle size. Fine PM with aerodynamic diameters less than 2.5 and 1 μm (PM_{2.5} and PM₁, respectively) typically poses greater health risks (Oberdörster *et al.*, 2005; Anderson *et al.*, 2012;) and exhibits higher correlations with visibility than coarse PM (PM₁₀) (Zhao *et al.*, 2013; Li *et al.*, 2017). Over the past decade, PM pollution has become a serious environmental problem in most urban regions in developing Asian countries, such as China and India (Bhaskar and Mehta,

2010; Tiwari *et al.*, 2014; Cheng *et al.*, 2015). Previous studies have investigated the horizontal distribution and temporal variation of surface-level PM concentration and their relationships with meteorological conditions in China (Li *et al.*, 2015; Wang *et al.*, 2015b; Zhang *et al.*, 2015). However, the vertical distribution and evolution of PM concentrations, which directly affect near-surface air quality and radiation transfer in the atmosphere, have been rarely reported, mainly because of a lack of observations.

The common methods of measuring vertical profiles of PM concentration in situ include tower measurement, LiDAR detection, and balloon sounding. The vertical distribution of PM concentrations can be measured continuously by gauges at different altitudes on a tower. For example, Deng *et al.* (2015) analyzed the evolution of PM₁, PM_{2.5}, and PM₁₀ concentrations at 121 and 454 m on the Canton tower in Guangzhou, China, from November 2010 to May 2013. They observed more uniform vertical distributions for fine PM than coarse PM and during summer than winter. Chan *et al.* (2005) investigated the characteristics of vertical profiles of PM_{2.5} and PM₁₀ in urban Beijing during August 2003 using tower observations at 8, 100, 200, and 325 m.

They reported that strong temperature inversions near the surface (< 50 m) and more stable conditions aloft enhanced the near-surface accumulation of pollutants. However, tower-measured PM vertical profiles often suffer from poor vertical resolution and limitation of detection height (several hundreds of meters at maximum). Using optical principles, fine-resolution vertical profiles of PM concentrations can be retrieved from aerosol extinction coefficients measured using LiDAR. Nevertheless, LiDAR measurements usually have a blind zone near the surface, on the order of several dozens of meters in height where pollution is most concerned (Li *et al.*, 2019). Balloon sounding can be used monitor PM concentrations using optical- or diffusion charging-based sensors with a high vertical resolution (several meters), and can measure standard meteorological variables simultaneously. Balloon sounding released frequently enough can successfully capture the vertical distribution and evolution of atmospheric PM during haze and fog episodes (Bisht *et al.*, 2016; Zhang *et al.*, 2017; Han *et al.*, 2018).

The vertical distribution and evolution of PM concentrations are affected by the dynamic and thermodynamic structures of the planetary boundary layer (PBL). A great deal of research effort has been made to investigate the mechanisms of air pollution formation associated with PBL structures (Ding *et al.*, 2005; Hu *et al.*, 2014; Tang *et al.*, 2015; 2016; Zhu *et al.*, 2016; Yang *et al.*, 2017; Li *et al.*, 2018a, b; Zhu *et al.*, 2018; Miao *et al.*, 2019; Liu *et al.*, 2019). For example, Sun *et al.* (2013) investigated the impact of PBL structure on the evolution of tower-measured PM_{2.5} concentrations at three levels in the near-surface layer in Beijing, during a summer haze event (August 1–16, 2009). Han *et al.* (2018) analyzed the vertical distribution and evolution of PM_{2.5} concentrations and their relation to PBL structure during a prolonged haze episode (December 20–25, 2015), over central-eastern China using measurements from a tethered balloon. Wang *et al.* (2019) studied the PBL vertical structure over Beijing urban area and its effect on LiDAR-derived aerosol extinction coefficient during air pollution episodes from December 1 to 4, 2016. These studies mostly focused on individual air pollution episodes lasting for several days. Regular or long-term characteristics of PM vertical distribution and their associations with PBL structures have rarely been reported.

Northeast China had the second highest surface concentrations of PM₁, PM_{2.5}, and PM₁₀ in China during 2006–2014 (second to the North China Plain) (Wang *et al.*, 2015b). Unlike other regions in China, surface PM concentrations in Northeast China have exhibited an increasing trend over the past several years (Wang *et al.*, 2015b). The characteristics of the vertical distribution of PM and its relationship with PBL structures in this region remain unclear. Only a few studies have examined the vertical distribution of aerosols during several air pollution episodes in Northeast China. Dickerson *et al.* (2007) investigated the impact of a cyclonic system on the vertical distribution and transport of dust and gaseous pollutants (CO, SO₂, and O₃) from the PBL to the free troposphere over Northeast China using aircraft observations in April 2005. Ma *et al.* (2018) analyzed the vertical distribution of aerosol extinction

coefficients and derived PM_{2.5} concentrations using a ground-based LiDAR in Shenyang, Northeast China, during two air pollution episodes from December 2016 to January 2017. However, the impact of PBL structures on aerosol vertical distribution in Northeast China has rarely been studied (Li *et al.*, 2019).

Shenyang, a provincial capital, is one of most populated cities in Northeast China (Fig. 1(a)), with a population of 7.37 million in 2017 (National Bureau of Statistics of China; <http://data.stats.gov.cn/search.htm>). Air pollution occurs frequently in this city during autumn and winter, mainly due to enhanced local emissions (e.g., coal burning for energy and crop-residue burning) and pollutant transport from adjacent polluted regions such as the North China Plain (Li *et al.*, 2018a, b; Ma *et al.*, 2018; Miao *et al.*, 2018; Li *et al.*, 2019). In this study, we examined the impact of PBL structures on the evolution of aerosol vertical distributions in Shenyang, a provincial capital city in Northeast China, on both monthly and episodic time scales. Fine-resolution vertical profiles of PM₁, PM_{2.5}, and PM₁₀ concentrations and meteorological parameters in the PBL were measured using intensive balloon soundings in Shenyang during November 1–31, 2018.

The remainder of this paper is organized as follows. Section 2 introduces the observational sites, data and methods. Section 3 analyzes the characteristics of PM vertical distributions and their relations to PBL structures during the observational period and during four air pollution episodes. Finally, conclusions are drawn in Section 4.

DATA AND METHODS

Vertical Profiles of PM Concentrations and Meteorological Parameters

Two observation stations less than 8 km apart were located in the southern urban region of Shenyang (Fig. 1(b)). At the balloon sounding station (BSS) (123.42°E, 41.68°N), we measured fine-resolution vertical profiles of PM₁, PM_{2.5}, and PM₁₀ concentrations and some meteorological parameters [including air temperature (T_a), wind speed (WS), and wind direction (WD)] during November 1–31, 2018. The radiosonde detection system (Model Chuangzhi Tan Kong-1) was developed by the Institute of Atmospheric Physics of the Chinese Academy of Sciences. Balloons were released eight times a day during the periods November 1–9, 15–16, and 25–30, starting at 02:00 local time (LT) at intervals of 3 h, and at 02:00, 08:00, 14:00, and 20:00 LT on all other days. The ascending velocity of the sounding balloons was about 2.5 m s⁻¹, and sounding data were recorded at intervals of 1 s. The detection duration was about 20–30 min, and the detection height usually reached up to 1500–2800 m.

Fine-resolution vertical profiles of PM concentrations were measured using a low-cost laser particle matter sensor (Plantower PMS-5003T, China). A fan in the sensor draws air through a chamber where PM with diameters of between 0.3 and 10 µm are detected by a 90°-scattered laser-induced light, with the wavelength estimated at 650 ± 10 nm (Kelly *et al.*, 2017). The light-scattering signals are subsequently placed into different PM size bins of 0.3–1 µm, 1–2.5 µm,

Fig. 1. (a) Geographical location of Shenyang, and (b) the locations of balloon sounding station (BSS) and national weather station (NWS) in Shenyang, with background representing land use type.

and 2.5–10 μm , and then mass concentrations of PM_{10} , $\text{PM}_{2.5}$ and PM_{10} are calculated, with a detection resolution and range of $1 \mu\text{g m}^{-3}$ and 0–500 $\mu\text{g m}^{-3}$, respectively. The low-cost PM sensors had good performance in field studies, compared to some scientific grade instruments (e.g., TEOM, Thermo Fischer Scientific Inc., USA) (Kelly *et al.*, 2017; Zheng *et al.*, 2018; Bulot *et al.*, 2019; Sayahi *et al.*, 2019). They have been also used for research on air quality and health risk assessment in different regions and countries, such as India, China, and the United States, in recent years (Masic *et al.*, 2017; Sakhnini *et al.*, 2018; Camprodon *et al.*, 2019; Nelson *et al.*, 2019).

In addition, vertical profiles of T_a , WS , and WD were simultaneously measured at the BSS, with a detection resolution of 0.1°C , 0.1 m s^{-1} , and 0.1° , respectively. All of the radiosonde data (including PM and meteorology) were averaged every 10 m in the vertical direction after data quality control. Vertical profiles of potential temperature (θ) were also calculated to examine variation in atmospheric stability.

The reliability of balloon sounding data was evaluated using the measurements aerosol extinction coefficients from a ground-based LiDAR (located at 41.74°N , 123.43°E) for November 1–3 and conventional meteorological sounding data from a L-band radiosonde system at the national weather station (NWS) (located at 123.51°E , 41.74°N) in Shenyang at 08:00 and 20:00 Local Time (LT) for each day in November 2018 (see Appendix A). Detailed information on the aerosol LiDAR and the L-band radiosonde system can be found in Li *et al.* (2019). Evolution of the vertical distribution in $\text{PM}_{2.5}$ concentrations measured using the balloon sounding were basically consistent with that of the aerosol extinction coefficient from November 1 to 3, 2018. Both observed that aerosols increased and were transported at higher altitudes with time during this period, and mostly accumulated at altitudes below 0.5 km and near 1 km at night on November 2 (Fig. S1). The vertical distribution of θ and WS measured at BSS also varied consistently with that observed at NWS during the entire study period (Fig. S2).

Surface PM concentrations and Meteorological Parameters

The hourly mean mass concentrations of PM_{10} and $\text{PM}_{2.5}$ near the surface were obtained from 11 national air quality monitoring stations in Shenyang. The averaged PM concentrations from the 11 stations (representing the mean air quality in the city) were used to identify air pollution episodes during the study period, and to evaluate the variation trend of near-surface PM concentrations measured using balloon sounding. The distribution and detailed information of each station were reported previously (Li *et al.*, 2017). To explain the potential long-range transport of air pollutants from the North China Plain to Shenyang, we also selected hourly mean $\text{PM}_{2.5}$ concentrations at another 24 cities (20 cities in North China Plain and 4 in Liaoning province) in November 2018. In addition to surface-level PM monitoring data, surface meteorological observations, including hourly mean WS , WD , T_a , relative humidity (RH), and atmospheric visibility (Vis) in November 2018, were obtained from the NWS.

Wind Fields from European Centre for Medium Range Weather Forecasts Reanalysis Data

Reanalysis data from The European Centre for Medium Range Weather Forecasts (ECMWF) were used to reproduce the horizontal flow fields at 10 m height over the North China Plain and Liaoning province during two air pollution episodes in November 2018. The horizontal meridional and zonal wind speeds (u and v) were obtained at 02:00, 08:00, 14:00, and 20:00 LT each day, with a spatial resolution of $0.125^\circ \times 0.125^\circ$.

Determination of Planetary Boundary Layer Height

Planetary boundary layer height (PBLH) directly determines the vertical dilution range of air pollutants, and thus affects surface air quality. We applied the 1.5- θ -increase method (Nielsen-Gammon *et al.*, 2008) and the critical bulk Richardson number (R_i) method (Stull, 1988) to determine the PBLH in the daytime and nighttime, respectively, using

balloon sounding data. The former method defines the PBLH as the altitude where θ first exceeds the minimum θ -value within the boundary layer by 1.5 K, while the latter determines the PBLH as the lowest altitude where R_1 is larger than 0.25. The two methods have been widely used in previous studies to analyze PBL structures and their effects on air pollution (Hong, 2010; Seidel *et al.*, 2012; Hu *et al.*, 2014; Guo *et al.*, 2016; Li *et al.*, 2018a, 2019; Yang *et al.*, 2019).

Occurrence Frequency of Unstable Conditions

The occurrence frequency of unstable conditions at different altitudes and hours, $f(H_n, t)$, is calculated according to Eqs. (1) and (2), to quantitatively analyze the diurnal variation in the thermodynamic structure of the PBL.

$$\delta\theta(z, t) = \delta(z + 1, t) - \theta(z, t) \quad (1)$$

$$f(H_n, t) = \frac{\text{Num}(\delta\theta(H_n < z < H_{n+1}, t) < 0)}{\text{Num}(\delta\theta(H_n < z < H_{n+1}, t))} \quad (2)$$

We calculated the difference in θ at two adjacent altitudes for different hours, $\delta\theta(z, t)$, with z and t being observational height and time, respectively. If $\delta\theta(z, t) < 0$, this represents unstable conditions at the given height and time. Thereafter, we counted the number of times unstable conditions occurred within each 100 m vertical range at different hours (the numerator in Eq. (2), with $H_n = 0, 100, 200, \dots, 1600$ m), and found the proportion of this frequency in relation to the

total sample number at the same heights and hours. Finally, the mean diurnal variation of $f(H_n, t)$ was calculated for November 2018.

RESULTS

Vertical Distribution of PM Concentrations and Meteorological Parameters during November 2018

Fig. 2 shows the evolution and vertical distributions of PM₁, PM_{2.5}, and PM₁₀ concentrations below 2 km and the temporal variation of hourly mean surface-level PM_{2.5} and PM₁₀ concentrations in Shenyang during November 2018. Overall, the vertical distributions of PM₁, PM_{2.5}, and PM₁₀ concentrations showed similar evolution to each other and had consistent trends with the surface-level PM_{2.5} and PM₁₀ concentrations during the observation period. An aerosol-rich layer persisted below 0.3–0.6 km and sometimes extended up to 1.5–2 km and even higher altitudes during the study period except on November 16 when a cold front system passed over Shenyang. PM concentrations typically decreased with an increase in height, mainly due to enhanced emissions near the surface, and dry deposition of aerosols. This is consistent with long-term tower observations from other cities, such as Guangzhou (Deng *et al.*, 2015), and episodic measurements using aerial vehicles in the Yangtze River Delta (Wang *et al.*, 2015a; Lu *et al.*, 2019) in China. The inverse was also observed at times, where PM concentrations increased with height, particularly during some pollution episodes. This is discussed in Section 3.4.

Fig. 2. Height-time cross-sections of mass concentrations of (a) PM₁, (b) PM_{2.5}, and (c) PM₁₀, and (d) variation of surface PM_{2.5} and PM₁₀ concentrations in Shenyang during November 2018. Rectangles represent air pollution episodes.

Four air pollution episodes, characterized by the maximum hourly mean surface $\text{PM}_{2.5}$ and PM_{10} concentrations greater than 100 and 150 $\mu\text{g m}^{-3}$, respectively, were distinguished in November 2018 in Shenyang. The first pollution episode (EP1) occurred from 16:00 LT on November 1 to 07:00 LT on November 4, EP2 occurred from 15:00 LT on November 7 to 01:00 LT on November 10, EP3 occurred from 11:00 LT on November 14 to 12:00 LT on November 15, and EP4 occurred from 02:00 LT on November 25 to 02:00 LT on November 27, 2018. During the four air pollution episodes, the maximum surface-level hourly mean $\text{PM}_{2.5}$ (PM_{10}) concentrations reached 117 (178), 142 (209), 187 (245), and 240 (284) $\mu\text{g m}^{-3}$, respectively, and near-surface PM concentrations measured using balloon sounding also increased significantly.

To understand the evolution of PBL structure and surface meteorological conditions during the study period, Fig. 3 shows the vertical distributions of θ and WS below 2 km and variation of hourly mean T_a , RH , WS , WD , and visibility at a height of 2 m during November 2018 in Shenyang. The variation of surface T_a and WS measured at the NWS was consistent with that of θ and WS measured using balloon sounding. Regular diurnal variation of θ , T_a , and RH was observed on most days in this month, with higher temperature and lower RH in the daytime. Potential temperature inversions usually occurred at night due to the infrared radiative cooling of the surface. During all air pollution episodes, low visibility (< 2 km), high RH ($> 80\%$), and frequent changes in WD were observed near the surface. However, WS exhibited large differences among different episodes. Strong winds near the

surface ($WS > 6 \text{ m s}^{-1}$) and at higher altitudes ($WS > 15 \text{ m s}^{-1}$) were observed during EP1 and EP4, indicating that both episodes were probably related to the transport of air pollutants, while weak winds dominated in EP2 and EP3.

Diurnal Variation of Vertical Distribution of PM Concentration

The mean diurnal variation of the vertical profiles of PM_1 , $\text{PM}_{2.5}$, and PM_{10} concentrations within 1.5 km above the surface in November 2018 in Shenyang are shown in Fig. 4. On average, PM concentrations decreased with height at all hours. At night (02:00, 05:00, 20:00, and 23:00 LT), PM concentrations decreased rapidly with height below 500 m, with average lapse rates of 5.8, 9.7, and 11.7 $\mu\text{g m}^{-3}/100 \text{ m}$ for PM_1 , $\text{PM}_{2.5}$, and PM_{10} , respectively, and changed slowly aloft. In the daytime (08:00–17:00 LT), PM concentrations were distributed more uniformly in the vertical direction; the smallest concentration lapse rates of about 1.8, 3.0, and 3.8 $\mu\text{g m}^{-3}/100 \text{ m}$ below 500 m were observed at 14:00 LT for PM_1 , $\text{PM}_{2.5}$, and PM_{10} , respectively. Aerosols were mostly distributed below 400 m at night, but were transported to higher altitudes (up to $\sim 800 \text{ m}$) during the daytime due to strong convective turbulence.

Using aerial vehicle observations, Lu *et al.* (2019) also observed that the vertical gradient of $\text{PM}_{2.5}$ concentrations decreased from the morning to the afternoon due to the diurnal variation of the PBL structure, on 5 days between August 2014 and February 2015 in a suburban area in Lin'an, China ($29^\circ 56' - 30^\circ 23' \text{N}$, $118^\circ 51' - 119^\circ 52' \text{E}$). Due to the enhanced turbulence between 13:00 and 18:00 LT, the

Fig. 3. Vertical distributions of (a) potential temperature and (b) wind speed, and temporal variation of (c) air temperature, (d) relative humidity, and (e) wind speed and direction at 2 m height, observed in Shenyang during November 2018.

Fig. 4. Monthly averaged vertical profiles of PM_{10} , $\text{PM}_{2.5}$, and PM_1 concentrations at (a) 02:00, (b) 05:00, (c) 08:00, (d) 11:00, (e) 14:00, (f) 17:00, (g) 20:00, and (h) 23:00 LT, observed at Shenyang in November 2018. The blue bar represents the standard deviation of $\text{PM}_{2.5}$ concentrations.

ratios of PM_{10} concentration at heights of 100 and 320 m to those at 8 m increased by 5% and 13%, respectively, compared to the daily mean ratios, and the mean ratio of $\text{PM}_{2.5}$ between 100 and 8 m heights even ranged from 101% to 120%, according to tower observations in Beijing in August 2003 (Ding et al., 2005).

On average, higher PM concentrations were observed near the surface at night than during the daytime, partly due to diurnal variation of the PBL structure. Similar diurnal variation was also observed in the surface-level PM concentrations at air quality monitoring stations in Shenyang during this study period (not shown) and in different seasons in 2014 and 2015 (Li et al., 2016).

To examine the proportions of airborne fine and coarse particles at different levels, Fig. 5 shows the mean vertical distributions of concentration ratios of $\text{PM}_1/\text{PM}_{2.5}$, $\text{PM}_{2.5}/\text{PM}_{10}$, and $\text{PM}_1/\text{PM}_{10}$ at different hours averaged in November 2018 in Shenyang. Fine particles accounted for a large proportion of aerosols at all altitudes; the monthly averaged ratios of $\text{PM}_1/\text{PM}_{2.5}$ and $\text{PM}_{2.5}/\text{PM}_{10}$ below 1.5 km ranged from 0.53 to 0.96 and from 0.65 to 1, respectively. The ratios of $\text{PM}_1/\text{PM}_{2.5}$ and $\text{PM}_{2.5}/\text{PM}_{10}$ remained about 0.6 and 0.8 below 0.5 km at night and below 0.6–1.0 km in the daytime, and aloft they exhibited larger fluctuations and an increasing trend with height. The $\text{PM}_{2.5}/\text{PM}_{10}$ ratio approached one at altitudes of 1.3–1.5 km, which was mainly because coarse particles typically show stronger dry deposition than fine particles. The annual mean ratios of surface-level $\text{PM}_{2.5}/\text{PM}_{10}$ in Shenyang from 2010 to 2012 ranged from 0.69 to 0.73 (Zhao et al., 2013), and their monthly mean ratios ranged between 0.50 and 0.81 from 2014 to 2015 (Li et al., 2016). These values are close to the near-surface ratios observed in this study.

Impact of PBL Structure on Diurnal Variation of PM Vertical Distribution

The diurnal variation of PM vertical distributions is closely related to the diurnal evolution of PBL structures. As shown in Fig. 6, the vertical profiles of θ at night averaged

in November 2018 exhibited stronger atmospheric stability than those in the daytime. Between 20:00 and 05:00 LT, the θ -difference from the surface to 200 m height increased from 0.14 to 0.26 K, due to continuous radiative cooling of the surface after sunset. Stronger atmospheric stability suppressed vertical mixing of aerosols and trapped more aerosols near the surface. During the daytime, atmospheric stability became weak because of solar heating of the surface; a small vertical gradient of θ was observed below 0.3 km at 08:00 LT and below 1 km at 14:00–17:00 LT on average. Strong convective unstable conditions favored vertical transport of aerosols and resulted in a more uniform vertical distribution of PM concentrations.

To show the diurnal evolution of atmospheric stability more clearly, the diurnal mean occurrence frequency of unstable conditions at different altitudes, averaged for November 2018 is displayed in Fig. 7. Unstable conditions occurred more frequently during 08:00–17:00 LT than during other times, with the highest frequency observed at 14:00 LT. Unstable conditions occurred frequently ($> 35\%$) below 0.1 km at 08:00 LT, and extended up to more than 1 km at 14:00 LT, which reflected the growth of the PBLH and corresponded to the vertical mixing range of aerosols. Unstable conditions also occurred at night at altitudes between 0.5–1 km altitudes, with the highest frequency being larger than 30%, probably caused by low-level jets (LLJs). LLJs often occur within the boundary layer and are characterized by a pronounced diurnal cycle in winds with the maximum occurring at night (Du et al., 2014a). As shown in Fig. 6, stronger wind speed and wind shear were observed in the PBL at night, with the maximum mean WS close to 8 m s^{-1} at altitudes of 400–600 m. Previous studies have shown that LLJs affect the transport and dispersion of air pollutants in the PBL (Hu et al., 2013a, b; Klein et al., 2014; Wei et al., 2018; Miao et al., 2019; Wang et al., 2019). LLJs occur more frequently in Northeast China than most other regions in China (Du et al., 2014b), potentially modifying the vertical distribution of aerosols in Shenyang.

Fig. 5. Monthly averaged vertical profiles of $PM_1/PM_{2.5}$, $PM_{2.5}/PM_{10}$, and PM_1/PM_{10} ratio at (a) 02:00, (b) 05:00, (c) 08:00, (d) 11:00, (e) 14:00, (f) 17:00, (g) 20:00, and (h) 23:00 LT observed at Shenyang in November 2018.

Fig. 6. Vertical profiles of potential temperature and wind speed at (a) 02:00, (b) 05:00, (c) 08:00, (d) 11:00, (e) 14:00, (f) 17:00, (g) 20:00, and (h) 23:00 LT observed at Shenyang averaged over November 2018.

To further quantify the impact of atmospheric stability on the vertical distribution of PM concentrations, the relationship between vertical gradient of PM concentration and θ between 200 m and the surface are shown in Fig. 8. The vertical gradient of PM concentrations increased with increasing atmosphere stability (represented by the difference between θ at the surface and at 200 m). When the vertical gradient of θ between 200 m and the surface increased by 1 K, the differences of PM_1 , $PM_{2.5}$, and PM_{10} concentrations at the two levels increased by about 4.9, 8.9, and 10.5 $\mu g m^{-3}$, respectively. Thus, the increase in atmospheric stability favored the trapping of more pollutants in the near-surface layer, and resulted in deterioration of air quality near the surface at night.

Impact of PBL Structure on Vertical Distribution of PM Concentrations during Air Pollution Episodes

The impacts of PBL structures on the vertical distribution

of PM concentrations were further examined during the four air pollution episodes, to help understand the formation and mechanisms of air pollution in this region. Fig. 9 shows the vertical profiles of $PM_{2.5}$ concentration, WS , and θ during EP1 and EP4; both episodes were likely related to the long-range transport of pollutants. During EP1, the near-surface $PM_{2.5}$ concentration was greater than 200 $\mu g m^{-3}$ and decreased sharply with height at 20:00 LT on November 2. The strong potential temperature inversion layer and low wind speed near the surface favored the accumulation of pollutants in the shallow stable surface layer. Subsequently, nocturnal LLJs developed during the period from 20:00 LT on November 2 to 08:00 LT on November 3. Here, we identified LLJs following the method in Du *et al.* (2014b) using two criteria: (1) the maximum WS is more than 10 $m s^{-1}$ below 4 km (occurring below 1 km as boundary layer jets and between 1 and 4 km as synoptic-system-related LLJs); and (2) the WS must decrease by at least 3 $m s^{-1}$ between the

Fig. 7. Mean diurnal variation of vertical distribution of occurrence frequency of unstable conditions for November 2018 in Shenyang.

Fig. 8. Relationship between vertical gradient of PM concentrations and potential temperature during November 2018 in Shenyang. The bar represents the standard deviation of PM concentration differences of all samples in each bin.

height of the maximum and minimum wind speed, the minimum being aloft. As shown in Fig. 9(b), the jet core occurred at altitudes between 0.4 and 0.6 km and the maximum WS reached 16–18 m s^{-1} , identifying these as boundary layer jets. With enhancement of boundary layer jets, aerosols were transported from the upstream regions to Shenyang (Fig. 10(a)), and then trapped in a residual layer at nighttime. As a result, $\text{PM}_{2.5}$ concentrations between 0.7 and 1.2 km heights increased significantly during 23:00 LT on November 2 and 08:00 LT on November 3. After sunrise, WS in the PBL decreased and a deep convective boundary layer (CBL) developed, with the top of the CBL reaching about 1.1 km at 14:00 LT on November 3. Note that EP1 experienced the warmest weather ($\sim 20^\circ\text{C}$ near the surface) during November 2018 (Fig. 3(c)), which favored the development of CBL. Meanwhile, the pollutants trapped in the residual layer on the previous night were vertically mixed in the CBL due to strong convective turbulence, which led to a uniform vertical distribution of $\text{PM}_{2.5}$ concentration below 1.1 km and an increase of near-surface $\text{PM}_{2.5}$ concentration. Similar processes were also reported in other air pollution episodes in different regions, such as O_3 pollution over the southern Great Plains of the USA (Klein *et al.*, 2014) and over the Yangtze River Delta (Hu *et al.*, 2018), and $\text{PM}_{2.5}$ pollution in Beijing (Sun

et al., 2013) and in Northeast China (Li *et al.*, 2019).

During EP4, Shenyang was located ahead of a cold front system (not shown). WS in the PBL increased from 10 to 25 m s^{-1} during 02:00–17:00 LT on November 26 (Fig. 9(e)), which can be identified as the synoptic-system-related LLJs, and the surface hourly mean WS increased from near zero to 8 m s^{-1} (Fig. 3(e)) due to large gradients of surface air pressure. The strong southwesterly winds transported large amounts of pollutants from the North China Plain to Shenyang (Fig. 10(b)), leading to a continuous increase in $\text{PM}_{2.5}$ concentration in the PBL. Meanwhile, strong wind shear weakened atmospheric stability and favored the growth of the PBLH and the vertical mixing of pollutants in the PBL. The PBLH ranged from 1.0 to 1.3 km during the daytime (Figs. 9(e)–9(f)). At 20:00 LT on November 26, WS in the PBL decreased, but a nocturnal boundary layer jet, with a jet core at an altitude of about 250 m, was observed. Meanwhile, a stable boundary layer with a depth of 250 m decoupled from a residual layer above it. This PBL structure greatly determined the vertical distribution of $\text{PM}_{2.5}$ concentrations. In the stable surface layer (< 250 m), $\text{PM}_{2.5}$ concentration remained high at the surface and decreased rapidly with height. Influenced by LLJs, $\text{PM}_{2.5}$ concentration was small and uniformly distributed between 250 and 400 m. Aerosols

Fig. 9. Vertical profiles of (a, d) PM_{2.5} concentration, (b, e) wind speed, and (c, f) potential temperature in Shenyang during EP1 on November 2–3 and during EP4 on November 26, 2018.

Fig. 10. Wind fields at 10 m height retrieved from the ECMWF reanalysis data over the North China Plain and Liaoning province at (a) 08:00 LT on November 2 and (b) 14:00 LT on November 26, 2018. Circles denote PM_{2.5} mass concentration at different cities averaged (a) from 00:00 LT on November 2 to 12:00 LT on November 3 during EP1, and (b) on November 26 during EP4. SY represents the locations of Shenyang.

that cannot be transported/deposited to the surface accumulated at the bottom (400–600 m) of the residual layer due to the stable conditions and weak WS, while at higher altitudes PM concentration decreased gradually with height.

The 10 m winds retrieved from ECMWF reanalysis data at 08:00 LT on 3 November 2018 (EP1) and 14:00 LT on 26 November 2018 (EP4) are overlaid by PM_{2.5} concentrations averaged for episodic events at 25 cities in the North China Plain and Liaoning province, in Fig. 10. The long-range transport of aerosols during these episodes can be clearly observed. The episodic-mean PM_{2.5} concentrations exceeded 100 and 200 μg m⁻³ during EP1 and EP4, respectively, for most cities in the North China Plain. These values were much higher than those observed in Liaoning province, including Shenyang. Strong southwesterly and southerly flows

dominated the North China Plain and Liaoning province in both pollution episodes, giving favorable conditions for the transport of air pollutants to Shenyang.

In contrast to EP1 and EP4, both EP2 and EP3 were mainly related to local emissions in the presence of weak winds. During EP2, a deep CBL in the daytime gradually turned into a shallow stable surface layer at night (Fig. 11(c)). The PBL height decreased from 0.8 km to below 0.3 km from 14:00 LT on November 7 to 02:00 LT on November 8, while WS in the PBL increased gradually with time. Correspondingly, PM_{2.5} concentration (~90 μg m⁻³) was distributed uniformly in the CBL in the daytime, while at night the near-surface PM concentrations increased gradually because of the strong potential temperature inversion and stagnant WS near the surface. Another PM concentration peak was observed

Fig. 11. Vertical profiles of (a, d) PM_{2.5} concentration, (b, e) wind speed, and (c, f) potential temperature in Shenyang during EP2 on November 7–8 and during EP3 on November 14–15, 2018

in the residual layer at night at altitudes of about 250–350 m due to strong atmospheric stability. At 08:00 LT on November 8 after sunrise when the convective boundary layer began to develop due to heating of the surface (according to the vertical profile of θ), PM_{2.5} concentration was mixed uniformly in the shallow unstable layer below 150 m. Above this altitude, PM_{2.5} concentration decreased rapidly from 120 to $40 \mu\text{g m}^{-3}$ because the vertical transport of aerosols was effectively hindered by the θ -inversion layer capped on the CBL. During EP3, the decrease of PBLH and strong stable θ -inversion layer caused an increase of PM_{2.5} concentration near the surface. With the enhancement of nocturnal LLJs, the aerosols between 0.3 to 1.2 km also increased at 02:00 LT on November 15. During the four air pollution episodes, the vertical distribution of PM concentration/surface air quality was closely related to the thermodynamic (related to atmospheric stability) and dynamic structures (largely influenced by LLJs) of the PBL.

CONCLUSIONS AND DISCUSSIONS

Using intensively collected radiosonde data of PM₁, PM_{2.5}, and PM₁₀ concentrations and meteorological parameters in Shenyang during November 2018, we investigated the characteristics of aerosol vertical distributions, and the impact of PBL structures on their mean diurnal variation, and during four air pollution episodes. The main conclusions can be summarized as follows.

(1) Diurnal variation in the PBL structures affect the mean diurnal evolution of vertical distribution of PM concentrations. On average, aerosols were distributed in a shallower layer (< 400 m), and had higher near-surface concentrations and greater decreasing rate with an increase in height, due to stronger atmospheric stability at night, compared to the daytime.

(2) The impact of the thermodynamic structure of the PBL on the vertical distribution of aerosols was clearly demonstrated during four air pollution episodes. PM tended to be trapped in a shallow stable surface layer (usually < 300 m) and in the lower part of a residual layer (250–500 m) when atmospheric stability was strong at night; stable stratification effectively suppressed the vertical mixing of aerosols. During the daytime, aerosol particles were mixed uniformly in the PBL (with gradually increasing height up to approximately 1 km) due to enhanced convective turbulence, which subsequently influenced the surface air quality.

(3) The PBL dynamic structure, dominantly affected by LLJs (both boundary layer jets and synoptic-system-related LLJs) in EP1 and EP4, strongly influenced aerosol transport and dispersion processes and modified the atmospheric stability and PBLH, therefore influencing the formation of air pollution. Strong southwesterly and southerly flows caused by LLJs transported amount of pollutants from the North China Plain to Shenyang during EP1 and EP4. Weak winds in EP2 and EP3 favored the accumulation of pollutants from local emissions.

(4) Previous studies of LLJs in Northeast China have focused on their impact on precipitation in summer (Du *et al.*, 2014b), but their impact on the formation and distribution of air pollution in this region has rarely been reported (Li *et al.*, 2019). It is necessary to investigate the characteristics (such as occurrence frequency and intensity) of LLJs in Northeast China during autumn and winter, and explore their relation to the formation of air pollution. This will likely be beneficial for improving the early warning and forecasting of air pollution episodes.

(5) Long-term and multi-site observations are needed to provide a full understanding of the characteristics of aerosol vertical distribution, and the formation and evolution of air

pollution in Northeast China. Comparative studies at different sites in urban, suburban, and rural areas will help clarify the effects of anthropogenic activities (including anthropogenic emissions, urban heat island effects, and so forth) on aerosol vertical distributions and air pollution.
