ABSTRACT

The recognition that the spread of COVID-19 is primarily through airborne transmission has brought renewed urgency to understand the spread of aerosols generated from patients. Viral-laden aerosols generated from oral coughs have been well studied; however, aerosols generated from nasal sneezing has been overlooked. This scenario arises from patients who suffer allergic rhinosinusitis, or the nasal cavity is irritated, particularly during naso-endoscopy. Nasal sneezing is characterised by an explosive blast of air exiting the nostrils, which can be considered as dual jets, resulting in the spread of viral-laden aerosols remaining suspended in the air. This study used computational fluid dynamics consisting of a hybrid RANS-LES turbulence method to model the airflow and the discrete phase model to track aerosol dispersion during nasal sneezing. The results demonstrated that the exhaled airflow jets during nasal sneezing resemble the flow characteristics of two parallel jets in co-flow. These two jets interfere with each other in the merging zone, and after they merge, the sneeze plume expands radially. The nasal sneeze forms a V-shaped plume with smaller particles in the core region. At the end of the sneeze, when the exhaled jets have lost their initial momentum, the large particle dispersion is dominated by gravity. We detected the presence of a ‘sneeze puff’ that transport droplets away from the body, similar to the buoyant puff observed in recent COVID-19 studies of oral coughs.

Keywords: Aerosol dispersion, CFD, Sneeze jet, Nasal cavity, Droplet evaporation

1 INTRODUCTION

It is widely accepted that the spread of COVID-19 is highly transmissible by airborne transmission, arising through the inhalation of viral-laden aerosols exhaled through coughing or sneezing from an infected person (Arumuru *et al.*, 2020; Diwan *et al.*, 2020). Aerosols exhaled through coughing, sneezing, talking, and breathing by an infected person introduces an inhalation exposure risk to nearby people for respiratory infection. Direct close contact of large particles produced by coughing or sneezing is approximately one meter (Leder and Newman, 2005; Morawska, 2005), while aerosols introduced by sneezing and coughing can travel for 7–8 meters (Bourouiba, 2020).

Aerosols from an infected person can be generated from oral coughs (Johnson *et al.*, 2011), singing (Bahl *et al.*, 2021), and exhalation (Philip *et al.*, 2021). However, medical procedures can also generate aerosols, known as aerosol-generating procedures (e.g., tracheal intubation, tracheotomy, cardiopulmonary resuscitation). An overlooked scenario is aerosol generation from nasal sneezing despite how common allergic rhinosinusitis is among the general population. Furthermore, when the nasal cavity is irritated, such as during naso-endoscopy, or inflamed, the nose experiences a tickly, itchy sensation leading to sneezing.

During nasal sneezing, the soft palate closes, and the tongue elevates to guide the ejected air from the lungs through the nose (Mygind and Dahl, 1998). High momentum jets are discharged from both nostrils and simultaneously interact with each other and the ambient air. However, up to now, numerical studies have primarily focused on characterising aerosol-cloud formation from coughs, sneeze, and talking produced from the oral cavity (Johnson *et al.*, 2011; Lee *et al.*, 2019; Wang *et al.*, 2020; Stadnytskyi *et al.*, 2021; El Hassan *et al.*, 2022), as well as aerosol dispersion inside a room (Inthavong *et al.*, 2013; Heschl *et al.*, 2014; Ji *et al.*, 2018; Tao *et al.*, 2020; Bathula *et al.*, 2021; Crawford *et al.*, 2021; Shah *et al.*, 2021; Shrestha *et al.*, 2021) and outdoor environments (Feng *et al.*, 2020; Gorbunov, 2021). Additionally, studies (Zhu *et al.*, 2006; Scharfman *et al.*, 2016) demonstrated the oral cough produced a droplet-laden cough jet and puff dynamics, as well as review articles on the fluid dynamics of respiratory droplets (Dbouk and Drikakis, 2020; Mittal *et al.*, 2020; Katre *et al.*, 2021), and mitigation strategies for reducing viral transmission (Hui *et al.*, 2012; Khosronejad *et al.*, 2020; Salati *et al.*, 2021).

Ge *et al.* (2021) modelled a cough jet for 10 s of physical time and showed that higher room temperatures caused a shorter cough jet and droplet penetration. Behera *et al.* (2021) showed that the cough jet temporal evolution is similar to that of a continuous free jet and that the jet travelled approximately 1.1 m in half a second. With co-flow, the jet travelled faster and further. Fabregat *et al.* (2021) showed a cough jet in two parts, the initial jet stage and a dissipative phase over which turbulence intensity decayed.

Previous studies have investigated the influence of indoor ventilation on aerosol distribution. The flow path between the contaminant source and the exhaust vent is crucial for controlling the airborne aerosol. The contagion is better managed when the exhaust is closer to the patient source (Thatiparti *et al.*, 2017). Cao *et al.* (2015) characterised the interaction between a downward jet plane and virus-laden particles within a room. The results demonstrated that utilizing downward jet with high velocities reduces inter-personal exposure to coughed particles. Feng *et al.* (2021) performed a parametric analysis to investigate how a portable ultraviolet's operating conditions impacted the filtration efficiency in a patient room. The filtration efficiency was defined as reducing the concentration of suspended virus-laden droplets escaping from the room into the central ventilation system. They concluded that the air cleaner's higher ventilation flow rate provided the highest filtration efficiency.

These previous studies mainly focused on the aerosol expelled from the mouth, and nasal sneezing has not been considered. An irritant often triggers nasal sneezing to the nose, whether a pollutant or invasive medical treatments (e.g., nasoendoscopic inspection). The established findings (Feng *et al.*, 2020; Fontes *et al.*, 2020) of oral cough jets demonstrated that expelled droplets maintain their initial momentum with the airflow jet direction. However, two co-flowing jets are moving together for nasal sneezing, which is expected to demonstrate different airflow and aerosol dispersion than oral sneezing and coughing.

There is a relation between the droplet size and viral loading based according to Poisson distribution (Anand and Mayya, 2020). A virus has a discrete nature, and viral incorporation into the droplets expelled from humans depends on the statistical fluctuations (Duguid, 1946). An experimental study revealed that the viral loading is higher in larger particles (Alonso *et al.*, 2015). The same finding (Zuo *et al.*, 2013) stated that the virus-laden droplet size distribution transition towards larger particles following a power law with an exponent greater than three.

Due to the rapid transmission of the COVID-19 worldwide, the spread of the injected aerosol from sneezing or coughing is a critical concern (Zhang *et al.*, 2020). While previous studies have investigated oral coughs, few have examined the airflow dynamics of the human exhalation flows during nasal breathing. Salati *et al.* (2021) investigated the airflow dynamics of nasal respiration with and without an N95 respirator at 30 L min⁻¹ respiration rate. The results demonstrated that the exhaled airflow jets from the nostrils move downwards and impinge on the respirator's internal surface. Wei *et al.* (2016) estimated the fraction of the exhaled airflow re-inhaled during the respiration cycle in a pediatric airway replica. They concluded that a very small fraction of the exhaled air volume is re-inhaled in the following breathing cycle. Gupta *et al.* (2010) investigated the nasal airflow jets during respiration. They characterised the nasal breathing exhaled jets by two front angles and two side angles. These three studies so far (Gupta *et al.*, 2010; Wei *et al.*, 2016; Salati *et al.*, 2021) examined the exhaled airflow jets during regular breathing cycles, which lasts more than 1.65 s. However, during nasal sneezing, the blast of exhaled air through the nostrils

lasts for approximately 0.4 s, producing different flow characteristics and aerosol dispersion. During nasal sneezing, the droplet injection is located at the nostril, and the airflow coming out from the nostrils is directed towards the ground. Therefore, the airborne viral transmission between people will be different during nasal sneezing. To better understand the transport dynamics of the virus laden aerosols through the air during nasal sneezing, this study applied a hybrid RANS-LES turbulence model to investigate the fluid and particle characteristics of the nasal airflow jets during a 0.4 s sneeze and how they interact with each other.

2 METHOD

2.1 Computational Geometry Model

The geometry of a seated manikin was used for this study (shown in Fig. 1). A human nasal cavity, extracted from CT scans used in previous studies (Zhang *et al.*, 2019; Inthavong *et al.*, 2020), was included to produce natural exhalation conditions. The nasal airway included the nasopharynx, the paranasal sinuses, and the main nasal passage and the surrounding domain was a room with a floor size of 2 m × 2.2 m and a height of 2.4 m. The right and left nostril

Fig. 1. (a) Geometry of a seated manikin with an internal nasal cavity that generates the exhaled airflow, (b) Preliminary steady state flow to establish the human thermal plume, (c) Optimised mesh with highly refined region in the sneeze region, and (d) Zoomed view of the internal nasal cavity that generates the exhaled sneeze.

openings had a cross-sectional area of 41.1 mm² and 40.0 mm², respectively. The model was meshed with poly-hex-core cells and prism layers on the nasal cavity walls using Ansys-Fluent 2019R3. A preliminary mesh was created to establish the exhalation and sneeze plume, and then it was refined (using a body-of-influence) in this region. The highly optimised final mesh contained 3.97 million cells with a concentration of cells in the exhalation plume region (Fig. 1(c)).

2.2 Airflow Modelling

A steady simulation was initially performed to establish a natural convection thermal plume flow (Fig. 1(c)). The model was then switched to a transient simulation, and the scale-resolving $k-\omega$ SST-SBES (Stress Blended Eddy Simulation) model was used (Van Strien *et al.*, 2021). This applies the $k-\omega$ SST model in the near-wall region and a Large Eddy Simulation model away from the wall with the switch between the two accomplished using a blending function. Here the WALE subgrid-scale model was used. Large eddies are resolved directly in the LES region, while small eddies are modelled. The subgrid-scale (SGS) stresses resulting from the filtering operation are unknown and require modelling. The subgrid-scale turbulence models in ANSYS Fluent employ the Boussinesq hypothesis (Hinze, 1975) as in the RANS models, computing subgrid-scale turbulent stresses from:

$$\tau_{ij} - \frac{1}{3}\tau_{kk}\delta_{ij} = -2\mu_t \bar{S}_{ij} \quad (1)$$

where μ_t is the subgrid-scale turbulent viscosity. The isotropic part of the subgrid-scale stresses τ_{kk} is not modelled directly but added to the filtered static pressure term. $\bar{S}_{ij}$ is the rate of strain tensor for the resolved scale defined by

$$\bar{S}_{ij} = \frac{1}{2} \left(\frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) \quad (2)$$

In this case, the WALE subgrid-scale model was used, in which the eddy viscosity is modelled by:

$$\mu_t = \rho L_s^2 \frac{(S_{ij}^d S_{ij}^d)^{\frac{2}{3}}}{(\bar{S}_{ij}^d \bar{S}_{ij}^d)^{\frac{5}{2}} + (S_{ij}^d S_{ij}^d)^{\frac{5}{4}}} \quad (3)$$

where L_s and S_{ij}^d in the WALE model are defined, respectively, as:

$$L_s = \min \left(\kappa d, C_\omega V^{\frac{1}{3}} \right) \quad (4)$$

$$S_{ij}^d = \frac{1}{2} (\bar{g}_{ij}^2 + \bar{g}_{ji}^2) - \frac{1}{3} \delta_{ij} \bar{g}_{kk}^2 \quad (5)$$

where

$$\bar{g}_{ij} = \frac{\partial \bar{u}_i}{\partial x_j} \quad (6)$$

d is the distance to the nearest wall, $\kappa = 0.41$ is the von Karman constant, and $C_\omega = 0.325$ is the WALE constant. With this spatial operator, the WALE model is designed to return the correct asymptotic (y^3) behaviour for wall-bounded flows.

Conservation of energy gives

$$\frac{\partial}{\partial t}(\rho e_i) + \nabla \cdot (\rho \vec{v} h_i) = -\nabla \cdot (k_{eff} \nabla T - \sum h_j \vec{J}_j) + S_{hi} \quad (7)$$

where e_i and h_i are the internal energy and enthalpy of species i . k_{eff} is the sum of the laminar thermal conductivity arising from the turbulence modelling. The diffusion term is defined below and S_{hi} arises due to the source term arising from the particle coupling.

The conservation equation for the mass of species i gives:

$$\frac{\partial}{\partial t}(\rho Y_i) + \nabla \cdot (\rho \vec{v} Y_i) = -\nabla \cdot \vec{J}_i + S_{yi} \quad (8)$$

where S_{yi} is the rate of production by evaporation from the dispersed phase. Mass diffusion of water vapour between the air from the nasal cavity with the external surrounding air occurs through Fick's Law:

$$\vec{J}_i = -\left(\rho D_{i,m} + \frac{\mu_t}{Sc_t}\right) \nabla Y_i - D_{T,i} \frac{\nabla T}{T} \quad (9)$$

where Sc_t is the effective Schmidt number for the turbulent flow:

$$Sc_t = \frac{\mu_t}{\rho D_t} \quad (10)$$

and $D_{T,i}$ is the Soret coefficient.

2.3 Aerosol Modelling

The equation of motion for the particles (droplets) is given by:

$$m_p \frac{d\vec{u}_p}{dt} = \vec{F}_d + m_p \vec{g} \quad (11)$$

where the subscripts p and g represent particle and gas (air) phases, m_p is the particle mass, $\vec{g}$ is the acceleration due to gravity and F_{dm} is the drag force per unit mass given by:

$$F_{dm} = \frac{18\mu}{\rho_p d_p^2} \frac{C_d Re}{24} (u_g - u_p) = \frac{(u_g - u_p)}{\tau} \quad (12)$$

where τ is the particle relaxation time.

A dynamic drag coefficient was used to account for variations in the droplet shape when an initially spherical droplet moves through a gas. The slip velocity between the droplet and gas contributes to the droplet distortion and is significant when the Weber number is large. In this case, the peak droplet Weber number was estimated (at peak sneeze velocity) to be in the order of 0.3 to 3 based on $We = \rho_g v^2 d_p / \sigma$ where the peak velocity was estimated as 30 m s^{-1} , $\sigma = 0.07194 \text{ N m}^{-1}$, and the range of diameters was 20 to $200 \mu\text{m}$. This suggests relatively weak distortion and breakup, but it could be more significant in larger droplets. The dynamic drag coefficient accounts for the effects of droplet distortion, linearly varying the drag between that of a sphere to a value of 1.54 corresponding to a disk (Liu *et al.*, 1993). This is defined as:

$$C_d = C_{d,sphere} (1 + 2.632y) \quad (13)$$

where

$$C_{d,sphere} = \begin{cases} 0.424 & Re > 1000 \\ \frac{24}{Re} \left(1 + \frac{1}{6} Re^{\frac{2}{3}} \right) & Re < 1000 \end{cases} \quad (14)$$

y is the droplet distortion, given by the second-order ordinary differential equation:

$$\frac{d^2 y}{dt^2} = -\frac{C_d \mu_l}{\rho_l r^2} \frac{dy}{dt} - \frac{C_k \sigma}{\rho_l r^3} y + \frac{C_F}{C_b} \frac{\rho_g}{\rho_l} \frac{u^2}{r^2} \quad (15)$$

The constant terms have values of $C_F = 1/3$; $C_k = 8$; $C_D = 5$; $C_b = 1/2$ from O'Rourke and Taylor (1987)'s Taylor Analogy Breakup model. Droplet breakup that occurs for $We \gg 1$ is modelled with the Schmehl model (Schmehl *et al.*, 1998) breakup, which can distinguish between three breakup regimes, Bag Breakup Multimode Breakup, and Shear Breakup, based on the droplet Weber and Ohnesorge number. For water droplets, the Ohnesorge number is $Oh = \mu_l / \sqrt{\rho_l D \sigma_l}$ ($Oh < 0.1$).

Multicomponent particles were selected to model the sneeze droplets. The particle mass m is the sum of the masses of the components:

$$m = \sum_i m_i \quad (16)$$

The component mass fraction in this study was set to 0.9524 for liquid water and 0.0476 for the non-volatile viral species. A heat balance equation governs the droplet temperature

$$m_p c_p \frac{dT_p}{dt} = h A_p (T_g - T_p) - L \frac{dm}{dt} \quad (17)$$

which calculated the droplet temperature from a heat balance involving convection and evaporation.

The onset of droplet vaporisation occurs when the temperature of the droplet reaches the vaporisation temperature T_{vap} and continues until the droplet's volatile fraction is completely consumed. In Ansys Fluent, the onset of the vaporisation law is determined by setting the value of T_{vap} Which is a modelling parameter that has no physical significance. To ensure the droplet evaporation rates are consistent with reported values, the T_{vap} alue was evaluated against Redrow *et al.* (2011), shown in Fig. 2(a). As the ambient relative humidity increased, the T_{vap} setting value increased to match the results of Redrow *et al.* (2011). Fig. 2(a) compares the evaporation of pure water droplets with different sizes obtained from the current study and Redrow *et al.* (2011). The presence of a non-volatile or soluble component affects the water vapour pressure over the droplet surface and affects the evaporation rate. Therefore, the final size distribution of multi-component droplets will differ from pure water droplets (e.g., 50% of the original size for a solute content of 88 g L⁻¹ (Nicas *et al.*, 2005; Anand and Phuleria, 2021)). Fig. 2(b) shows the droplet temperature reach a steady value equal to T_{vap} .

2.4 Boundary Condition

The nasal cavity mucosal wall temperature was set to 34°C at a fully saturated state, while the nasal vestibule lined with nasal hair has a zero-water vapour mass flux. The temperature setting was based on septal mucosal temperature measurements, ranging from 30.2°C at the end of inspiration to 34.4°C at the end of expiration during exhalation (Fabricant, 1957; Lindemann *et al.*, 2002). The exhaled airflow starts at the naso-oropharynx exit, which is assumed to have a fully conditioned state of 34°C and 100% saturation due to it originating from the lungs. The manikin surface temperature was set to 30°C; clothing thermal resistance was not included, reducing the manikin temperature further. A preliminary steady-state simulation was performed to establish a natural convection thermal plume flow (Fig. 1(c)). The air density was defined with

Fig. 2. (a) Droplet evaporation profile comparison with Redrow *et al.* (2011) at different ambient relative humidity, (b) Droplet temperature profile during evaporation at different ambient relative humidity, (c) Exhaled flowrate profile for sneezing, with labels for the start and end times of droplet injection, and (d) Sneezing droplet size distribution defined by a Rosin-Rammler distribution defined by $Y_d = e^{-(d/\bar{d})^n}$ where $\bar{d} = 13.5 \mu\text{m}$, and $n = 0.5$ to match the measured size distribution of Chao *et al.* (2009).

an incompressible ideal gas law (using the general equation of state) to allow a buoyant flow and thermal plume around the human body

2.5 Breathing Profiles

A sneeze profile from Gupta *et al.* (2009), which was curve fitted with sine functions, was utilised in this study and is defined as:

$$\dot{m} = A \sin(Bt + \sin(Bt)) \quad (18)$$

where $A = 0.0024465 \text{ kg s}^{-1}$, and $B = 7.853982 \text{ s}^{-1}$. Over the period of 0.4 s, the profile gives an equivalent exhalation tidal volume of 350 mL. This is less than the average breathing tidal volume of 500–550 mL; however, short sneezes and coughs may not necessarily expel the full volume and is assumed to be recovered in subsequent respiration cycles. The mass flow rate breathing profiles were converted into volume flow rates $\left(\dot{v} = \frac{\dot{m}}{\rho_{air}} \times 10^6 \right)$ shown in Fig. 2(c). The sneezed

droplets were defined by a Rosin-Rammler function based on measured droplet number distribution of a person coughing fifty times in Chao *et al.* (2009) (see Fig. 2(d)). The initial size range was divided into twenty-five discrete intervals at twenty locations on a plane and was introduced at time $t = 0.025$ s and at every $\Delta t = 5 \times 10^{-4}$ s until $t = 0.225$ s. The droplets were released at the internal nasal valve region (approximately 1 cm inside the nostril).

3 RESULTS

3.1 Nasal Sneezing Jets

The airflow velocity distribution is shown in Fig. 3 in planes that pass through the (A) left nostril, (B) nose centre, and (C) the right nostril. The left and right nostril jet entrained the ambient fluid and diverged radially with axial distance. The jet proceeded until its energy was ultimately dissipated due to viscous action at the small scales, resulting in jet decay. As the mass flow rate

Fig. 3. Velocity magnitude contours on planes that pass through the (A) left nostril, (B) nose centre, and (C) right nostril. (D) Velocity iso-surfaces of 1 m s^{-1} (blue), 5 m s^{-1} (yellow), and 10 m s^{-1} (orange) are overlaid on each other to depict the sneeze plume. Four snapshots during the sneeze are shown to demonstrate the sneeze plume evolution.

decreased over time, the high-velocity region near the nostril, known as the jet potential core, diminished. The nasal sneeze jets pass over the curved upper lip surface, and boundary layer separation occurs, which can be seen in the right nostril plane (Fig. 3(C)). The centre plane in Fig. 3(B) demonstrates the velocity distribution in a region where left and right nostril sneeze jets merged. Velocity iso-surfaces show high velocities ($\geq 10 \text{ m s}^{-1}$) are present up to $t = 0.2 \text{ s}$, however the residue momentum transports the sneeze jet into a slow moving puff (1 m s^{-1} in Fig. 3(D)). An animation of the sneeze jets over time is given in the Supplementary Material.

Fig. 4 shows instantaneous velocity profiles along six lines for both right and left planes at

Fig. 4. Velocity profile along monitoring lines on the (a) left and (b) right nostril planes.

different times. At $t = 0.1$ s peak velocities reached 23.4 m s^{-1} in the left plane and 28.3 m s^{-1} in the right plane, and these peaks diminished over time as the sneeze airflow reduced. There were multiple peaks in the right plane along line 2 and 3. The velocity profiles spread radially in Lines 4–6 for both planes.

Exhaled air through the human nostrils is similar to a circular free jet, although the exhaled jet is not necessarily a circular shape but dependent on nostril geometry. Furthermore, the two nostrils produce two co-flowing parallel jets. One jet is expected to have higher velocity due to the asymmetrical nasal cavity (e.g., left/right chamber) volumes found during nasal cycling. Nevertheless, we can refer to the behaviour of a circular free jet to provide insight into the mechanisms of nasal sneezing (dual co-flowing jets).

Circular free jets are characterised both radially and axially, where the radial jet flow is divided into three broad regions, namely, (1) the centerline region, (2) the shear layer, and (3) the outer layer (Heschl *et al.*, 2013; Miltner *et al.*, 2015). The centreline region typically exhibits a peak flow. However, the nostril opening is not circular in a nasal sneeze, and the peak velocity is not necessarily in the centreline region. In the shear layer region, vortices are formed, leading to energy transfer between turbulence structures of larger scales to smaller scales. Fig. 5 demonstrates the

Fig. 5. Sneeze plume development at $t = 0.1$ s, $t = 0.15$ s, and $t = 0.2$ s. The Q-criterion is used to display the resolved turbulent vortical structures present in the flow.

turbulence structures inside the sneeze puff visualised with a velocity iso-surface of 1 m s^{-1} . Each jet has a strong turbulent core with ring vortices surrounding it. The attachment of the right and left nostril jets can be observed at the front view of the velocity iso-surface (Fig. 5). The region from the nostrils to the point where the inner shear layer of the jets joins is called the 'converging region'. After the converging region, the jets started interfering, and the velocity on the centre plane increased to a maximum value (see Fig. 3). The 'merging region' is identified by the converging point and the points where the two jets resemble a single jet.

3.2 Sneeze Droplet Dispersion

Fig. 6(a) depicts the droplet dispersion with flow streamlines at $t = 0.05 \text{ s}$, demonstrating an initial linear moving jet that disperses at the end of the jet. The smaller droplets (blue colours) at the jet plume's edges display rollup effects caused by the flow streamlines. The flow streamlines show an air entrainment effect where recirculating flow occurs at the shear layer. The droplets were overlayed with the sneeze plume iso-surface of 1 m s^{-1} in Fig. 6(b) which shows some droplets move out of the plume suggesting gravitational sedimentation effects are prominent.

Fig. 7 shows the droplet dispersion from nostril sneezing coloured by diameter and velocity at different sneeze times. The larger sneeze droplets (red colour) travel further under its own inertia and gravitational sedimentation effects. The smaller sneeze droplets (blue colour) remain in the plume's core. At $t = 0.2 \text{ s}$, the sneeze plume exhibited a dominant vortex ring which quickly disintegrated into smaller vortex rings. The vortex ring entrains the smaller particles, and at $t = 0.4 \text{ s}$,

(a) Droplet dispersion with flow streamlines at $t = 0.05 \text{ s}$

(b) Droplet dispersion with sneeze plume at $t = 0.10 \text{ s}$, where the velocity iso-surface of 1 m s^{-1} is depicted

Fig. 6. Combined depiction of droplet dispersion (a) overlayed with flow streamlines at $t = 0.05 \text{ s}$, and (b) overlayed with a sneeze plume.

Fig. 7. Droplet size and velocity dispersion from a sneeze shown at different times of the sneeze.

these small rings exit the sneeze plume radially. At the end of the sneeze, the airflow is reduced, and the initial jet momentum dissipates. The larger droplets begin to settle under the influence of gravity. In contrast, the smaller droplets remain suspended in the air.

Fig. 8 shows the flow field state (temperature and velocity contours) at the end of the sneeze at time $t = 0.4$ s allowing a preview of the likelihood of viral exposure in close contact from the sneeze. The temperature contours show a persistent thermal plume accelerating upward from the head, while the sneeze temperature decreases towards the ambient air temperature. The velocity magnitude shows a peak velocity of 1.2 m s^{-1} at the most distal location from the nostril as the two nostril jets moved downwards.

The velocity components (Figs. 8(c), 8(d), and 8(e)) show a strong oscillatory motion in the x -direction (lateral, left to right direction), suggesting continuous mixing between the two jets. The y -velocity components show two distinct regions: A rising thermal plume above the head and a strong descending flow from the nostrils. The z -velocity (forward-back direction) contour shows a dominant forward motion, contributing to some droplets moving away from the jet as a sneeze puff. The highly mixed positive and negative z -velocity component suggests further oscillatory motion.

Fig. 8. (a) Temperature and (b) velocity magnitude contours in the nose centre plane at the end of the sneeze $t = 0.4$ s. Velocity component contours taken in the nose centre plane for (c) x-velocity, (d) y-velocity, and (e) z-velocity components.

4 DISCUSSION

According to World Health Organization (WHO), the SARS-CoV-2 virus can spread from an infected person by aerosols during coughing, sneezing, or breathing. While many studies investigated the dispersion of SARS-CoV-2 aerosols from the mouth due to coughing, aerosols from nasal sneezing have remained uninvestigated. Therefore, this study examined the exhaled jets and viral-laden aerosol dispersion during nasal sneezing. During nasal sneezing, the nostrils resemble converging circular nozzles that accelerate fluid. The airflow jets discharged from the nostrils expanded radially while moving axially. The mixing of these jets was similar to a co-flow parallel jet. During exhalation (breathing or sneezing), the air coming from the lung is partitioned between the nasal passages based on the cross-sectional area of each passage (Zhao *et al.*, 2004).

For nasal geometries with non-symmetrical nasal passages and nares, the interaction of the two parallel jets will alter, and the attachment of right and left jets occur at a shorter axial distance. In this study, the nasal passages and nostril dimensions were similar, but one side was more patent resulting in a faster jet in one nostril. The exhaled airflow jets produce maximum air velocities found in the

jet plume's core. This has been previously stated by Salati *et al.* (2021). The aerosols follow the direction of the exhaled flow while the jets have the initial momentum, and at the end of the sneeze, the dispersion will be dominated by gravity, which is shown by the y-velocity contours in Fig. 8.

There appears to be a '*sneeze puff*' similar to the cough puff that has been found from oral coughing (Fabregat *et al.*, 2021), evident by the droplets moving forwards away from the main jet flow (Fig. 6) and the z-velocity contours (Fig. 8(e)). According to the current literature (Leder and Newman, 2005; Bourouiba, 2020), aerosols exiting from the mouth can travel meters from the subject. The single circular jet exhaled from the mouth moves horizontally and carries the viruses considerably until the jet loses its momentum. However, the viral aerosols exiting the nostrils from nasal sneezing is orientated towards the ground, limiting the virus's travel distance. The results showed that the smaller viral droplets remained suspended in the air at the end of nasal sneezing. These droplets can be carried away by the indoor or outdoor air currents, which necessitates wearing a mask despite the social distancing.

The flow field state at the end of the sneeze ($t = 0.4$ s) shows a moving sneeze downwards and a horizontal vortex puff that is likely to continue dispersing the viruses throughout a room. Furthermore, the persistent thermal plume from the body will transport droplets upwards and can be assisted by a displacement type ventilation that moves air from the ground upwards. In this study, ambient air is at rest and room ventilation was not considered in the simulations. Air currents from room ventilation or thermal buoyancy can affect the exhaled airflow characteristics and aerosol dispersion. Nasal sneezing follows a breathing cycle which usually takes about 4 seconds. Further extensions of the current work can include a longer simulation time to understand the effect of respiration on exhaled flow and aerosol transport after nasal sneezing and evaluate the effectiveness of different ventilation systems to remove the viral droplets.

5 CONCLUSION

To complement the existing studies of cough jets from COVID-19 infected subjected, this study investigated viral-laden aerosols exiting the nostrils due to nasal sneezing. A seated manikin with a human nasal cavity was modelled to investigate the viral-laden aerosol dispersion and exhaled airflow jet characteristics from the nostril during nasal sneezing. A computational study of a human nasal sneeze was performed with using a RANS/LES turbulence model to provide realistic transient flow fields. From the results, the following conclusions were made:

- Exhaled airflows during nasal sneezing are similar to turbulent free jets in parallel.
- The right and left jets interfere with each other and merge after a specified axial distance.
- The jets lose their initial momentum as the sneeze mass flow rate decreases, and the jets diverge radially with axial distance.
- The sneeze aerosol plume can be categorized as V-shaped exiting the two nostrils. The particles larger than 150 microns sediment rapidly to the bottom of the plume due to the gravitational forces, while the smaller particles, less than 10 microns become suspended in the air within the fringes of the sneeze plume.
- A '*sneeze puff*' that transports the aerosols away from the body was identified, similar to the buoyant puff observed from oral coughs.
